Several trade exhibits were displayed during the Conference as well as exhibits by individual members. Of exceptional interest was a special exhibit of Old Exeter and Devonian Silver of the sixteenth, seventeenth and eighteenth centuries. The social side of the conference was not neglected. On Tuesday evening the Mayor gave a reception to the delegates at the Royal Albert Memorial, while the local committee entertained the delegates to lunch. The local programme included a visit to the Exeter Historical Museum and the Cathedral, where a short organ recital was given by Dr. E. Bullock. The party was afterwards conducted over the Cathedral. The delegates also paid visits to places of interest in the city. Miss M. Tothill, the curator, addressed the party on the St. Nicholas Priory, and an inspection was made of the Hall of the Weavers, Fullers and Shearmen, the Hall of the Vicars Choral and Bampfylde House. An address on the city monuments and regalia was delivered by the Town Clerk (Mr. H. Lloyd Parry) in the Guild Hall. An excursion took place to Bradfield, the home of the Waldron family, by invitation of Commander and the Hon. Mrs. Adams, while the Sheriff of Exeter entertained all the delegates at a garden party in the Rougement Gardens.

¹ The presidential address and the papers and discussions will be published in the *Museums Journal*, commencing August 1925.

University and Educational Intelligence

CAMBRIDGE—Mr. J. A. Carroll, Sidney Sussex College, has been appointed University lecturer in astrophysics. Mr. G. U. Yule, St. John's College, has been reappointed University lecturer in statistics. Dr. A. H. Evans, Clare College, has been appointed a member of the Council of the National Trust for Places of Historic Interest or Natural Beauty. A. Lourie, St. John's College, has been nominated to the Choate Memorial Fellowship at Harvard University. W. A. H. Rushton, Emmanuel College, has been elected to the Michael Foster Research Studentship in Physiology. C. S. Deakin, Queen's College, and W. B. C. Perrycoste, Sidney Sussex College, have been awarded the John Winbolt Prize for a joint dissertation on the "Theory of Transverse Oscillations of Girders."

The Botanic Garden Syndicate reports the addition of 85 specimens of rare species of the genus *Rosa*, presented by Mr. C. C. Hurst, also a valuable collection of species of *Iris*, mostly collected wild, from the executors of the late Hon. C. N. Rothschild. An alpine house has been presented to the Garden by Mr. J. Cherrington.

On the occasion of the meeting of the International Astronomical Union at Cambridge, the honorary degree of Sc.D. was conferred upon President Campbell, M. Baillaud, Prof. de Sitter, Prof. Nagaoka, and Prof. Schlesinger.

The joint coal-mining diploma of the Universities of Cambridge and Birmingham has been approved by the Board of Trade.

DR. G. M. SHRUM, who has been associated with the low temperature laboratory at the University of Toronto since its inception, has been appointed assistant professor in physics at the University of British Columbia, Vancouver, B.C.

THE following awards for the year 1925-26 have been made by the Salters' Institute of Industrial Chemistry and approved by the Court of the Company—1924-25 fellowships have been renewed to Mr. H. H. Evers, University of Liverpool, Mr. K. Knight Law, University College, Nottingham; Mr. H. S. Pink, University College, Nottingham, and University of Oxford, and Mr. V. E. Yarsley, the University of Birmingham. Fellowships have been awarded to Dr. R. Campbell, Armstrong College, Newcastle-upon-Tyne, and University of Oxford, and Mr. R. O. Gibson, University College, London. The Salters' Institute has also awarded 70 grants in aid to young men employed in chemical works in or near London to facilitate their further studies.

AT Budapest an English College is to be established under the auspices of the Ministry for Religion and Public Instruction. Each year twelve students of the College will proceed to Great Britain for further study in one or other of the Universities of Oxford, London, and Aberdeen. Three years ago, Hungary's economic situation was so desperate that an inter-university committee was formed to save scientific workers from having to abandon their work owing to lack of equipment and means of subsistence. In a report by Prof. Emile de Grösz on the three years' activities of this committee, it is stated that the Rockefeller Foundation has made grants for travelling scholarships and sends 70 periodicals in the English language, while a German society sends 261 German publications for the use of the universities, and the American Science Extension Committee proposes to arrange exchanges of American and Hungarian scientific workers.

Societies and Academies.

COPENHAGEN

Royal Danish Academy of Science and Letters, October 17.—C. Wesenberg-Lund. Contributions to the anatomy and biology of the genus *Zoothamnium*. During two years' study of *Z. geniculatum*, special attention has been paid to the so-called macrogonidia, their origin and significance for the formation of new colonies.

December 12.—N. E. Nørlund. A table of the Riemann zeta function.—Harald Bohr. New proof of a general theorem of Kronecker on diophantine approximation.

January 9.—N. Bjerrum and L. Ebert. On some recent investigations concerning transference numbers and amalgam equilibria in mixtures of strong electrolytes. Some new experimental investigations, which have been regarded as incompatible with the hypothesis of complete ionisation of strong electrolytes, are discussed and explained from the view-point of this hypothesis.

January 23.—C. G. Joh. Petersen. How do whales swim? Whales swim by moving the caudal fin up and down; this is accomplished by means of the tail with its strong muscles, whereas the proper muscles of the caudal fin give this fin the rigidity suitable to the speed. When the speed is high, only small movements are made, for which reason the animal then only appears to quiver, the movements, therefore, are difficult to observe.

February 6.—Th. Mortensen. Antarctic zoogeographical studies. The study of the marine fauna, especially the echinoderms, supports the theory of a previous land connexion between Antarctica and South America (the Magellanic region). The Kerguelen group must also have been directly connected with that region. On the other hand, the so-called "subantarctic" islands, New Zealand, the Auckland-Campbell Islands, do not, as regards their echinoderm fauna, belong to the subantarctic region, but form a part of the New Zealand region. The correspondences between the Australian and the New Zealand echinoderm faunas would seem to be more naturally explained through Wegener's continental drift theory.

February 20.—N. Bohr. On the law of conservation of energy. The attempts to develop an atomistic interpretation of directly observable phenomena have led us to recognise the necessity of revising the ideas hitherto underlying the description of natural phenomena. Our present conceptions would not seem to allow of a detailed description of atomic processes which presumes the law of conservation of energy, which occupies a central position in the classical description of Nature.—C. Tate Regan. Dwarfed males parasitic on the females in oceanic angler-fishes (*Pediculati Ceratolidae*). (Proc. Roy. Soc. London, B, vol. 97, 1925.)

SYDNEY

Royal Society of New South Wales, June 3.—A. R. Penfold. The essential oil of *Boronia citriodora* and the occurrence of citronellol. *B. citriodora* belongs to the snow regions where it thrives, being especially abundant around Cradle Mountain, Moina, Tasmania. The leaves and terminal branchlets yielded from 0.75 per cent. to 0.93 per cent. of a sweet odiferous oil containing citronellol (80 per cent.), citronellol esters (principally acetate with some valenianate, d-a-pinene, sesquiterpene, a paraffin (m.p. 64-65°C.), etc.

WASHINGTON.

National Academy of Sciences (Proc. vol. 11, No. 6, June).—O. E. Glenn: A note on the abundance of differential combinants in a fundamental system.—C. N. Moore: On the application of Borel's method to the summation of Fourier's series. Borel's method is not so effective as Cesàro's in summing Fourier's series but is more effective than ordinary convergence.—S. Lefschetz: (1) Intersections of complexes on manifolds. (2) Continuous transformations of manifolds.—H. S. Vandiver: Laws of reciprocity and the first case of Fermat's last theorem.—E. W. Berry: A species of *Musa* in the Tertiary of South America. Fossil seeds of a species of *Musa* have been found in the coal measures of the Cerros de Guadalupe and Montserrat, Colombia, in a horizon probably oligocene. The discovery supports the statements of old writers that the banana was a staple food in America in pre-Spanish times.—P. Sushkin: Outlines of the history of the recent fauna of palæarctic Asia. The fauna is divided into two groups characteristic respectively of the northern zone and the southern or High Asian zone. In the northern zone, the indications are that the Pliocene climate was humid and mild, later there was local glaciation followed by a dry, continental period with steppe invaded by woodland. High Asia is characterised by desert, mountain and dry highland types; they are of ancient origin, but their present dominance is recent. Types with broken distribution are characteristic of more fertile conditions. There was no large inland basin in High Asia, during the Tertiary.—A. H. Compton. On the mechanism of X-rays scattering. Bennett, using two point counters, one to receive the recoil electron and the other the scattered quantum, finds many simultaneous impulses, in accordance with quantum theory predictions. Simon and Compton, using stereoscopic cloud expansion photographs showing a recoil electron and a secondary β ray track produced by the scattered X-ray quantum, find that the tracks in the majority of photographs are in accordance with the quantum theory prediction. The evidence is thus against any spreading wave theory of radiation, which requires that there should be no correlation between the direction of the recoil electron and that of the effect of the scattered quantum.—D. C. Miller. Ether-drift experiments at Mount Wilson (see NATURE, July 11, p. 49).—H. N. Russell: The intensities of lines in multiplets. I. Theory; II. Observed data (see NATURE, May 30, p. 835).—R. A. Millikan and I. S. Bowen: New light on two-electron jumps. Whenever a given type of spectral line progresses linearly with atomic number (irregular doublet law), the electron jumps originating it take place between orbits of the same total quantum number. Hot-spark electrometry shows that series of two-valence atoms are characterised by five nearly equally spaced bars; three-valence atoms show four bars. These characteristics are due to the simultaneous jumping of two electrons. The movement of one electron disturbs the system, causing a fellow-electron to make a similar jump.—H. M. Evans and G. O. Burr: The anti-sterility vitamin fat soluble E. Rats fed on synthetic food mixtures of fat, carbohydrate and protein with an appropriate salt mixture and vitamins A and B grow well, but sooner or later develop complete sterility. In the male there is complete destruction of germ cells, but in the female ovulation continues though gestation is interrupted by the death and resorption of the developing. This condition can be remedied by feeding with certain single natural foods containing the new food factor, vitamin E. Vitamin E is fat soluble and remarkably stable

to heat, light and chemical change; it is present in many animal tissues, abundant in leaves and seeds and especially in the wheat embryo. Cod-liver oil is notably lacking in vitamin E.—Grace MacLeod, Elizabeth E. Crofts and F. G. Benedict: The racial factor in metabolism. Measurements on seven Chinese and two Japanese women in American colleges showed that the average metabolism of these orientals was about 10.4 per cent. less than that taken for American women. Even granting the latter should be decreased by 5 per cent., there seems to be a specifically lower metabolic rate for Chinese and Japanese women.—C. Voegtlin, J. M. Johnson and Helen A. Dyer. Protoplasmic action of copper and gold. In view of the relative mass of protoplasm and of salts of these heavy metals, and of the relatively large surface exposed, it is considered that even in very diluted solutions (1 in 10^7), sufficient metal ions are present to exert a toxic effect by chemical means. Glutathione and cysteine have a protective effect, suggesting that the normal toxicity is due to "asphyxia" from loss of the glutathione normally present in small quantities in tissues.—G. H. Parker: Activities of colonial animals. III. The interrelation of zooids in soft corals. A mechanical stimulus or light induces only local response in gorgonians: the zooids of *Renilla* are all affected by a local stimulus, suggesting an interconnecting nerve-net.—Lucy G. Taliaferro. Periodicity of reproduction, infection and resistance in bird malaria. Periodicity of occurrence of high values of mean size of parasites is unaffected throughout the infection, indicating that the rate of reproduction remains constant. Some destruction of merozoites always occurs, and this natural resistance factor increases in potency at the crisis and is maintained through the latent period.—Emma L. Fisk: The chromosomes of *Zea Mays*. A haploid number of 10 chromosomes and a corresponding diploid number of 20 have been found, except in Black Mexican sweet corn, which generally has 22 chromosomes.—F. G. Pease: Measurement of the spectroscopic binary star Mizar with the interferometer. The determinations are in good accord with the results from spectroscopic data.—F. H. Seares and P. J. van Rhijn. Distribution of the stars with respect to brightness and distance from the Milky Way (see NATURE, June 20, p. 948).—G. Stromberg: The general distribution of cosmic velocities. Group motion varies from 12 km. per sec. for the Cepheids of long period to about 300 km. per sec. for stars of maximum velocity dispersion, globular clusters and spiral nebulae; thus the solar motion is dependent on the class of object to which its motion is referred.

VIENNA.

Academy of Sciences, May 14.—F. Kerner-Marilaun: The influence of the variable elements of the earth's orbit on the form of the European temperature chart during the Tertiary epoch. By means of Spitaler's calculations for the temperatures of extreme land and sea climates, and by means of the author's own method of geographical temperature analysis, it is possible to fix limits to the range within which the distribution of temperature oscillated in Tertiary Europe. The influence of the astronomically determined temperature change on the plant world of the Tertiary is indicated, and the floral migrations of deciduous and evergreen plants.—G. Sachs: On decomposition of azimenthines by mercury. The actions on benzaethylamin, on benzalbenzylamin, and on benzalanilin of mercury chloride and of mercury acetate.—H. Handel-Mazzetti: New Chinese plants (xxxiv). Includes five sorts of *Quercus* and three of *Vaccinium*.

June 12.—K Przibram On coloration and luminescence by Becquerel rays —H Benndorf Outlines of a theory of the earth's electric field (I) —F Knoll. On pan-algebraic manifolds —W Olbrich New problems in projection —G Weissenberger, F Schuster and J. Lielacher. On organic molecular compounds (xiv.) Chlorophenol and bromoform —M. Kohn and G Soltesz On a new tri-bromo-phenol, the 1-oxy-3,4,5-tri-bromo-benzol, and a new tri-bromo-cresol, the 1-methyl-2-oxy-4,5,6-tri-bromo-benzol (Sixteenth communication on bromo-phenols) —M Kohn and L Schwarz Preparation of brominated α -naphthochinon (Seventeenth communication on bromo-phenols) —R. Dworzak Preparation of di-bromacet-aldehyd-acetal by direct bromination of paraldehyde. —J. Schorn Macroscopic study of the earthquake of March 26, 1924, and of its after-shocks —A. Schedler Microseismic study of the earthquake of March 26, 1924 —F. M. Exner On the interaction of water and gravel in rivers Theoretical, experimental and photographic work on the sandbanks of the River Mur, south of Graz. —H Handel-Mazzetti New Chinese plants New species of Hydrangea and Senecio —A Tauber On the integration of linear differential equations (Fifth contribution.)

June 18.—G. Weissenberger, F Schuster and J. Lielacher On organic molecular compounds (xv) Aromatic amines

June 25 —M Chiba On the tongue-jaw reflex of the same side and crossed sides —H Neudorfer. Construction of the principal tangent curves on net-surfaces —H Jacob Influence of various stimuli on the growth of morphologically dissimilar parts of plants Weak solutions of potassium chloride and other salts were used and experiments made with Impatiens, Syringa and Phaseolus Resting plant organs were made to grow. Similar salts influence the growth of pollen-tubes —L Mirskaja: Changes in plants produced by removing the blossoms. —A Smekal. On the influence of the pores of solid bodies on molecular mobility and rigidity. Crystals are generally considered to have a solidity which they do not really possess; the lattice structure is liable to microscopic or submicroscopic interruptions and the rigidity of the apparent crystal is much less than the real molecular rigidity Self-diffusion in solid salts may be an internal surface process. —G Klein and J. Kisser The assimilation of nitrates by higher plants. An inquiry into the stages between nitrate and amino-acid. On feeding Phaseolus and Zea with $-\text{NO}_2$ in sterile culture solutions, $-\text{NO}_2$ and NH_4 — appeared in the culture medium, and NH_4 — also within the plant —F Trauth Geology of the northern Radstatter-Tauern and their foot-hills

July 2 —M Kohn and L Schwarz On the chinoid product of oxidation of benzal-di- β -naphthol. —E Emich Further remarks on the rubidium- (caesium-) silver-gold-halogen salts. —J. Vogel: Investigations on rubidium- (caesium-) silver-gold-halogen salts. —E. Reichl Contributions to the knowledge of the isomorphic relations of the cupro- and silver halogen salts

British Optical Instruments.

PROGRESS in nearly every branch of scientific investigation is dependent on the provision of suitable measuring apparatus. As the science develops, an ever-increasing degree of accuracy of measurement is required, which in its turn involves a correspondingly higher degree of refinement in the measuring apparatus. Many of the measuring instruments employed are essentially of an optical nature, and thus the optical instrument maker has been truly described as the tool-maker for all branches of scientific investigation including his own. It is the function and the duty of such a tool-maker to keep himself familiar with the latest advances in science, so as to be able to understand or even to anticipate the requirements of the investigator, and to meet these requirements by the provision of suitable practicable devices. That the British optical instrument maker has successfully fulfilled this function was clearly indicated by Mr. F. Twyman, who, in his recent presidential address to the British Optical Instrument Manufacturers' Association, discussed the capacity of the industry for invention, development, and production. His survey contained a record of notable achievements in regard to instrument design and construction of which any body of workers might justly be proud.

The economic stringency and the increased competition experienced during the past few years have stimulated the industry to increased efforts towards perfecting the quality and widening the range of its products, and towards improving and increasing its equipment for producing. Technically, the industry is in a healthy condition. Its research organisation, the British Scientific Instrument Research Association, has already proved of inestimable value. In addition, many of the individual firms in the industry actively prosecute research in their own laboratories; and these investigations are not simply directed towards putting forward new processes or improvements, but are often of a fundamental nature. This activity in research is reflected in the numbers of papers which have been published in recent years in the Transactions of the Optical Society and elsewhere, giving results of many important investigations carried out by the scientific staffs of optical firms. Educational facilities in all branches of technical optics are provided in London at the Optical Engineering and Applied Optics Department of the Imperial College of Science and at the Northampton Polytechnic Institute. Thus, the scientific, technical, and educational equipment of the industry is such as to lead one to anticipate a continuance of the notable attainments which have characterised it in the past.

The story of these achievements of the British optical instrument industry has never been sufficiently proclaimed, and the industry's commercial activities have probably not equalled, in extent or intensity, its technical and scientific abilities. For many years, German optical instruments have held a high reputation. This reputation has been well-deserved. It has been built primarily on quality; but quality has been backed up by publicity, by advertisement, and by efficient commercial methods which, above all, rendered the selection and purchase of a suitable instrument a relatively simple matter. To-day, the products of the optical glass industry and the optical instrument industry of Great Britain are well able to compete with those of any other country, and in many directions they have established a distinct supremacy.

If an examination were made of similar types of optical glasses obtained through the ordinary commercial channels from British and from foreign makers, we believe that the results would show that the former are in several respects superior to the latter. It is unfortunate that no detailed authoritative statement on this subject has yet been published. In regard to microscopes, the best British stands have been, for long, unsurpassed, and many notable advances have recently been made in the optical parts. British microscope manufacturers have now provided a series of apochromatic objectives which are superior to any made in any other country. They have also introduced improvements in illuminating systems, a dark-ground illuminator having been developed which permits the use of higher powers than was hitherto possible.

The superiority of British camera lenses has been frequently demonstrated. Photographic lenses for aerial survey, the specification for which is particularly severe, have been supplied to foreign countries by British makers in open competition with the rest of the world. The photographic lenses of aperture $F/2$ recently produced in Britain were the first lenses of such great rapidity, and are still distinctly the best of their class. The only foreign-made lens of an equivalent speed covers about two-thirds the width of field of the British lens. The telephoto lens, which originated in Britain, has been improved so as to suit the varied and extended uses to which it is now being applied, and the British lens of this type still holds a foremost place.

For astronomical instruments and for instruments used in astrophysics, no country stands higher in reputation than Great Britain. Since the War, British makers of surveying instruments have re-designed most of their instruments, and have effected improvements, not only in design, but also in construction and in sub-

sequent performance. The quality of the instruments is indicated by the fact that satisfactory sales are being effected abroad in the face of particularly severe competition from other countries. The best British binoculars now being manufactured are a little better than the best of the same class made abroad, and in addition, binoculars have now been made here which have a larger field of view than any others at present on the market.

For many years, the premier manufacturers of range-finders in the world have been British, and before the War, foreign governments were probably their best customers. During these latter years, these manufacturers have continued to develop and improve their products, which for quality and efficiency are still unsurpassed.

British optical instruments for physical research form another branch with a deservedly high reputation. Complete equipments for dealing in a broad way with various special fields of research, such as the electron theory of matter, have been supplied by British manufacturers to laboratories in practically every country in Europe, as well as to the United States of America, Japan, and various parts of the British Empire. It is probable that most of the research of the world in certain fields of prime importance in modern physics is being done with British-made instruments.

On its own initiative, the optical instrument industry during the past ten years has developed apparatus for the testing of optical elements and optical instruments. This apparatus, in one or other of its various forms, will measure interferometrically the errors and imperfections of any kind of optical instrument, such as, for example, an astronomical telescope, a microscope, camera lens, or binocular. Photographs of the imperfections can easily be obtained, and these constitute unquestionable records. The apparatus is now in use in Britain and also in certain factories and State testing institutions abroad. It is thus possible for manufacturers to have applied to their lenses a test which is free from all elements of judgment, and to have the results stated in numerical measurement.

Enough has been said to show that, from a technical point of view, the British optical instrument industry is active and vigorous. The existence of such an industry is vitally essential to progress in science and to the healthy development of the nation. Close co-operation between the scientific investigator and the optical instrument maker will facilitate a continuance of that progress and development. Reference may be made in this connexion to recent investigations on filter-passing micro-organisms. Adequate instrumental facilities for investigations on such organisms were not in existence a year or two ago. The investigators knew the limita-

tions of their apparatus and knew what their requirements were. They placed their knowledge and requirements before the instrument maker, and in a comparatively few months were supplied with the instruments which enabled them to go further and deeper into their work and to obtain those important results which have recently been published. The work involved the construction of a microscope stand with an accuracy of focussing and a rigidity not provided by any existing stand, and also of an entirely novel combined illuminator, in which a high aperture dark-ground illuminator is mounted concentrically with, and encircling, a quartz condenser. The former secures visibility and is used to locate the micro-organisms, while the latter is used with ultra-violet light to obtain the image on the photographic plate.

Many examples could be given of the services rendered by the optician in the provision of special apparatus, often very complex and ingeniously designed, for the control of industrial processes. The efficiency of the British optical instrument industry has been, to a large extent, responsible for the rapidly growing use of optical projection apparatus in connexion with industry.

It is obviously in the interests of the scientific investigator, whether his work lies in the academic or in the industrial field, that there should be in the country in which he works, a progressive and efficiently equipped optical instrument-making industry. Such an industry does not exist on the production of specialised instruments alone. The more frequently recurring demands for instruments of the less elaborate types have also to be met. The production of these provides training and experience for the members of the industry. Production is regulated by demand. The greater the demand for British-made optical instruments, even of the simpler type, the wider will be the field from which may be recruited the craftsmen, the artists, and the scientific designers, all of whom are required in the production of many of the masterpieces which emanate from the optician's workshop or laboratory.

The contributions made by the optical instrument industry of Great Britain both to science and to industry entitle it to support and encouragement by every section of the nation. During times of peaceful progress, as much as during war and strife, a prosperous and active optical instrument industry is an important national asset, the influence of which may extend far beyond mere national boundaries. It should only be necessary for the users in Great Britain of optical instruments to be made fully aware of the industry's attainments and capabilities, and also of the range and quality of its productions, to ensure that such support and encouragement will not be lacking.

Modern Physics.

IN the older British universities the term natural philosophy is still used to denote one of the main branches of study. In 1747 we find Mr. David Young appointed to be "professor of natural and experimental philosophy" in the United College of St. Salvator and St. Leonard in the University of St. Andrews. In the Scottish universities, applied mathematics fell within the province of the department of natural philosophy. There lies before us an M.A. diploma of the University of Glasgow, dated 1863, signed, amongst others, by Gul. Thomson, *Phil. Nat. Prof.* There is something to be said for retaining the more sonorous designation natural philosophy, at least for official purposes, in preference to the more compact term physics. It is the science which treats of the general properties of natural bodies. "The philosophy of science," says Prof. Whitehead, "is the endeavour to formulate the most general character of things observed." The changes which have taken place in our outlook upon natural phenomena during the first quarter of the present century have been profound, but yet they must be described as evolutionary rather than as revolutionary in character. Not only have there been brilliant experimental discoveries, resulting in entirely new methods of investigation, but also during the same period new theoretical conceptions have been introduced by Planck, Einstein, and Bohr, which have led to much questioning as to the fundamentals of our philosophy.

These developments, which have been discussed in a very large number of special treatises, have tended to render many of the older text-books, if not obsolete, at least imperfect and incomplete. The time has now arrived when it appears necessary to make provision for the new knowledge by revised and extended treatment. The task is no easy one, partly because of the rapid accumulation of new material and partly on account of our imperfect grasp of the new theories

Another and very serious difficulty is the amount of mathematical knowledge and training required for the full appreciation of old and new theories alike. As Prof. Donnan says in his foreword to the volume by Prof. Haas:

"A sure understanding of the quantitative principles of physical science is nowadays a necessity for everybody—for the chemist, engineer, and physiologist as much as for the physicist. Nobody can afford to say that he is not a physicist and so expect to be forgiven for his ignorance. Nevertheless, the difficulty is a real enough one for the many who fear the mathematical reasoning and the wealth and subtlety of physical science."

This raises the important question of the relation between the teaching of mathematics and the teaching of physics. If, as is now the custom in most, if not all, British universities, the teaching of each subject is undertaken by a separate department, it is clearly desirable that the teacher of applied mathematics should be in sympathy with the experimental work of the science student, and if possible be himself in some sense an experimenter. To the reviewer, who has had experience of the Mathematical Tripos of former days, it seems only a truism to say that in a well-arranged university course the mathematical and experimental work should proceed side by side, acting and reacting upon each other to the mutual advantage of both.

In the Rouse Ball Lecture for 1924, Dr. Horace Lamb has emphasised the condition for mathematical progress stated by Fourier: "The profound study of Nature is the most fruitful source of mathematical discoveries." The tendency, which has unfortunately prevailed at Cambridge, to separate mathematics and physics into watertight compartments, must be strenuously resisted.¹ The same may be said, in perhaps lesser degree, of other branches of science.

(1) The problem referred to above has been encountered by Dr. Auerbach, of Jena, who states that his experience proves that a student who attends without preparation courses on the special branches of theoretical physics (mechanics, heat, electricity, optics) does not appreciate the meaning of the whole or understand the methods employed in obtaining the results. On the other hand, he found that an introductory methodical course (largely concerned with mathematical processes) attracted a large number of students, who afterwards attended special courses with much greater benefit. This volume is the outcome of such a preparatory course of lectures. The author starts with the fundamental principles and then proceeds to deal systematically with the methods, passing from ordinary language to the language of mathematics, from the elementary to the more advanced, from the infinitesimal to the statistical, from

the arithmetical to the geometrical. Examples illustrating the mathematical methods are drawn from all branches of physics. The resulting impression conveyed is that of a rearranged text-book of physics in which the subjects are now grouped so that each individual experiment or theoretical investigation serves as an illustration of a particular type of mathematical equation or method. Thus cubic equations are illustrated by the example of the equation of state of Van der Waals, maxima and minima by the greatest range of a projectile and the position of minimum deviation of a prism.

If the point of view taken by the author be conceded, the resulting treatise may be regarded as satisfactory, for the work has been well done and the exposition is clear. The title chosen is slightly misleading, as it does not convey to the casual reader the fact that by far the most important function of the book is to elucidate mathematical methods in their physical applications. In a book of this character dealing with complex functions, differential equations, and spherical harmonics, it is remarkable that vector methods are not introduced until page 407 is reached.

(2) In writing his text-book, Prof. Haas, of Vienna, states that his aim is to provide an exposition which, while modern in treatment and outlook, would give a survey of the present state of theoretical physics, its principles and problems, without going too far into details. On looking over the pages for the first time, it might be inferred that this was a book for the mathematical physicist. It is true that symbolic and vectorial methods are employed and the principal rules of differential and integral calculus are assumed, but let the non-mathematician take heart—he is led on by gradual stages from the more familiar to the more abstruse. Prof. Haas is a skilful teacher, and the earnest student who follows him with care should finish the volume with greatly widened knowledge and sincere appreciation of the help rendered. To quote again from the foreword by Prof. Donnan: "The whole structure of physical theory is built up piece by piece, with an exposition so sequent and crystal clear that we can pass through and understand the great luminous building without painful effort." This first volume deals with mechanics, with the general theory of vector fields, of vibrations, and of potential, and also with the theory of the electromagnetic field and of light. The important subject of atomistic physics is postponed to later volumes. In an appendix of 20 pages a convenient summary is given of the contents of Vol. I.

An eminent exponent of the principle of relativity is credited with the dark saying that the mathematician is never so happy as when he does not know

¹ See NATURE, vol. 114, p. 460, 1924.

what he is talking about! He rejoices in the breadth of his generalisations and may say with the poet:

"There are nine and sixty ways of constructing tribal lays,

And every single one of them is right."

Perhaps! But the historian may attach very different values to them as accurate or even approximate records of tribal history. It is often difficult to determine at what point in a mathematical argument some tacit assumption is made, the rejection of which would invalidate the subsequent reasoning. As a rule, Prof. Haas is very careful in this matter, but consider the statement on page 211: "It is *impossible* for a *single magnetic source to exist* by itself" (italics as in the original). This is said to be a fact which necessarily follows from the definition of magnetism. Doubtless—if the author's definition is accepted; but should the physicist isolate a magnetic pole to-morrow, the mathematician would have no difficulty in formulating a new definition of magnetism.

(3) The college text-book of physics by Prof. Stewart is of a more elementary character and does not call for detailed criticism. It should prove suitable for students who expect to specialise in agriculture or medicine, or for those who are taking physics as part of a general course in arts and science. The author realises that there is a more important purpose than that of merely giving useful information. "The great discoveries and applications of science, to which we are to-day so indebted, have been due primarily to the development and diffusion of what may be called the modern scientific method of reasoning. The study of physics offers unusual opportunity for acquiring this method." Stress is laid on the importance of grasping the fundamental principles of the subject; but only after the student has had the opportunity of becoming familiar with the facts, are deductions or generalisations made. The principles are illustrated by a large number of examples drawn from common experience. An interesting and valuable feature is the introduction of a chapter on meteorology, "the physics of the atmosphere," with special reference to the United States and Canada. The volume is well illustrated and is liberally provided with numerical problems.

(4) Dr. Arnold Berliner, editor of *Die Naturwissenschaften*, has faced and accomplished successfully the difficult task of revising his "Lehrbuch der Physik," which now appears in a third and enlarged edition. The author acknowledges his indebtedness to Profs. Geiger and Henning for assistance in dealing with the subjects of atomic physics, radioactivity, and heat. The amount of information contained in these 645 quarto pages, many of them closely printed, is extraordinary. The standard is about the same as that of

Ganot or Deschanel, but the range is wider, and modern work is discussed from the beginning of the book. As illustrating the mixture of old and new, we may note that the quantum theory of specific heat comes only six pages later than the description of Lavoisier's ice-calorimeter; a few pages further on follows a well-illustrated account of the steam turbine.

The author realises clearly the restrictions imposed upon him by the elementary character of the work. While this makes a certain breadth of treatment—even amounting to prolixity—inevitable, it demands many sacrifices as regards strictness of demonstration and fullness of detail. The stringent claims of the professional physicist must sometimes be disregarded, and on didactic grounds only what is essential must be retained. It is remarkable, however, how much can be accomplished without the employment of advanced mathematical methods. Not many authors, for example, would care to face the task of presenting in some half-dozen pages an outline of both the special and the general theory of relativity. It is open to question whether the author is justified in adopting the bold plan of stating the principles of thermodynamics, including Nernst's heat theorem, before giving an account of the fundamental methods of thermometry and calorimetry.

British physicists are, as a rule, generously treated, and quotations are made from the writings of Faraday, Maxwell and Tyndall; but it may be pointed out that, long before Helmholtz in a celebrated memorial lecture emphasised the work of Faraday, the latter had formed a clear conception of the existence of atoms of electricity. The sections dealing with the development of the electron theory deserve a special word of praise; these take up in turn the subjects of discharge in gases and the phenomena of ionisation, Röntgen radiation, radioactivity, and the structure of the atom. In the last-named section a very lucid and interesting picture is given of the atomic model due to Rutherford and Bohr, together with a short account of its application to the explanation of the hydrogen spectrum. The work of Moseley on X-ray spectra and that of Aston on isotopes is briefly described, and Einstein's photo-electric equation is discussed. The numerous diagrams, though reproduced on a small scale, are remarkably clear and add greatly to the value of the book.

Of special interest is the chronological table which fills the last three pages of the volume. This contains the names of the leading natural philosophers of all nations from A.D. 1500 to the present time, and shows at a glance the life-period and the contemporaries of each. Such a table in the form of a wall-chart would be invaluable in the lecture-room of any department of physics.

H. S. ALLEN.

Our Climatic Environment.

- (1) *Civilisation and Climate*. By Ellsworth Huntington. Third edition, revised and rewritten, with many new chapters. Pp. xix + 453. (New Haven: Yale University Press; London: Oxford University Press, 1924.) 23s. net.
- (2) *Principles of Human Geography*. By Ellsworth Huntington and Sumner W. Cushing. (Huntington Geography Series.) Third edition, revised. Pp. xviii + 430. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 15s. net.
- (3) *Climatic Laws: Ninety Generalisations with numerous Corollaries as to the Geographic Distribution of Temperature, Wind, Moisture, etc.; a Summary of Climate*. By Prof. S. S. Visser. Pp. 96. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 7s. 6d. net.

(1) FROM archæological studies in Asia and Central America, Prof. Ellsworth Huntington was convinced that at certain periods in the past the population of these regions was not only larger than at present, but also more energetic and progressive. He also found evidence that in the arid parts of Asia these more populous periods were blessed with a greater rainfall. Hence he developed the "pulsatory" hypothesis of climatic changes. This hypothesis has met with a considerable amount of criticism, the most obvious of the alternative views being that with proper irrigation the land is still capable of supporting a large population, and that the inhabitants have to thank their idleness and improvidence, or the lack of enlightened government, for conversion of their fields into deserts. It must be agreed that the present inhabitants of Mesopotamia or the Indians of Central America would provide very poor stuff on which to build up a great empire like those of antiquity. Huntington has frankly admitted the point, and has turned the tables on his critics by making the variation of human efficiency with changes of climate an essential part of his theories. In so doing he has achieved a great deal of useful work in what may be termed the science of "applied climatology."

The first edition of "Civilisation and Climate" appeared in 1916, and opened with a detailed analysis of the amount of work done under different climatic conditions by a number of groups of people, mainly in the United States. The conclusion arrived at was that the most favourable conditions for human efficiency were a mean temperature in the neighbourhood of 60° F., a moderate seasonal range, a moderate variability of temperature from day to day, and a considerable degree of "storminess," the latter condition providing a stimulating series of weather changes. The material

was good so far as it went, but being based mainly on a single country within the north temperate belt, it did not seem to provide a sufficient groundwork for a discussion ranging from the tropics nearly to the poles. In the third edition, the basis has been extended by a detailed discussion of the death rates in a number of large towns, in relation to daily and seasonal changes of weather.

The results confirm those obtained from measurements of work done under varying conditions, but the basis is still predominantly American. The mean annual temperature of the eastern United States ranges from about 50° F. in the north to 70° F. in the south, and the optimum temperatures for health and physical energy range from 58° F. in Connecticut to 68° F. in Florida. For mental energy the optimum is lower, but the data are few and incomplete. In the north, where buildings are warmed in winter, the average annual temperature in which people live is higher than the mean temperature of the open air, so that the conclusion can legitimately be drawn from Huntington's figures that people are healthiest and work best in the temperatures to which they are most accustomed. One would like to see this part of the book extended to include the work of native races in the tropics and in the far north, but it is admitted that the necessary data would be hard to obtain. The other climatic factors of efficiency, variability of temperature and weather, are not open to this objection to quite the same extent, and there seems to be no doubt that these factors are responsible for small variations of 2 or 3, perhaps 5 per cent. in the output of work. Whether these variations are large enough to be significant in human progress remains doubtful.

On the basis of the results for temperate eastern America, the author proceeds to calculate the energy value of the climate of each part of the globe. The formula employed is arbitrary, and perhaps assigns too much importance to temperature, but granting the initial assumption that the climate of New England is highly favourable, it appears to fulfil its purpose sufficiently well. This map of climatic energy is compared with a map of "civilisation," according to the opinions of fifty competent authorities. The agreement of the two maps is striking, and really forms the main justification for the book.

The concluding chapters deal with the civilisations of antiquity, and the opinion is expressed that they grew up along the storm belt when it lay much farther south than now. But in the efficiency formula the temperature terms predominate, and since these have admittedly not changed appreciably, this amounts to an assumption that the optimum temperature was also higher; in other words, that the needs of the human

species have changed since that date. Hence it seems that the effects of storminess and especially of rainfall need to be considered in greater detail, and quite apart from temperature. Criticisms such as these are, however, matters of detail; the book certainly succeeds in its main object, which is to bring out the importance of climate in human activity and well-being. It remains only to add that it makes very interesting reading and is well illustrated, while the general appearance is excellent.

(2) The "Principles of Human Geography" is a text-book dealing with the relation of man's activities to the environment in which he lives. The first nine chapters deal with the more strictly geographical aspect—latitude, land-forms, bodies of water, soil, minerals and sources of power—and show how these control human life in different regions. The remainder of the book deals with the influence of climate, through its effect on plants and animals and on human efficiency, according to the views of "Civilisation and Climate."

Each of the different climatic regions has its own series of plant and animal products and its especial climatic advantages and handicaps. In the regions where the "climatic energy" is least, man is the slave of his environment, while in more favourable climates he begins to overcome his handicaps and improve his opportunities. In this way arise a number of characteristic cultures, which are skilfully described and analysed. Finally we come to the regions of cyclonic storms, the fortunate inhabitants of which rise superior to their environment, reaching out to the ends of the earth to gather the products of all countries, and to dominate their weaker neighbours, and the last few chapters may be described as the epic of "cyclonic man."

The authors have kept a restrained and lucid style throughout, while the book is well printed and illustrated. Each chapter concludes with a series of interesting problems requiring independent research, and one can readily accept the authors' statement that the students tackle them with great enthusiasm and interest.

(3) "Climatic Laws," unlike the two preceding books, appears to be the result, not of original thinking, but of much reading. It presents ninety generalisations, which are considered to correspond with the "laws" of other sciences. The idea is good, but the author's methods result in a heterogeneous mixture of dogmatic statements. Some are so obvious that it does not seem necessary to commit them to writing (e.g. the "law" that days and nights vary in length in middle and high latitudes); some are not true (e.g. "There are for most places two diurnal maxima and two minima for precipitation. . . . The maxima usually are at 2-5 P.M.

and 3-6 A.M."); the remainder are useful summaries of facts. The book is also marred by several examples of loose writing. Its most valuable feature is the long list of references, but the author would have been well advised to quote more extensively than he has done and also to add a few pages of tables.

The Tetraphyllid Cestodes.

A Monograph on the Tetraphyllidea: with Notes on related Cestodes. By Dr. T. Southwell. (Liverpool School of Tropical Medicine. Memoir (New Series) No. 2.) Pp. xv + 368. (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd., 1925.) 20s. net.

THE most difficult group of helminth parasites to deal with from the morphological point of view is the Cestoda. They have superficially a very considerable resemblance to each other and an elaborate technique is necessary before their internal anatomy can be satisfactorily studied. The older naturalists in their classifications based their systems largely on the external characters—characters which in a colourless animal such as a tapeworm are unsatisfactory, and are rendered even more unsatisfactory by the extremely muscular nature of the parasite and the absence of any supporting skeleton to retain a permanent shape. Moreover, the complicated life-cycle of these animals has made confusion worse confounded and our knowledge of the whole group is in a very chaotic condition indeed.

At present four orders of Cestoda are generally recognised. These are (1) the Cyclophyllidea, which contains most of the common forms from mammals and birds and on that account has had the greatest amount of attention; (2) the Pseudophyllidea, which includes the Broad tapeworm of man and has recently been the subject of a monograph by Nybelin; (3) the Trypanorhyncha, which is at present in a state of the utmost confusion; and (4) the Tetraphyllidea, which is the subject of the present able monograph. To these four Dr. Southwell has added a fifth and smaller order, the Heterophyllidea. This new order is considered exhaustively in the present work.

Dr. Southwell has been engaged in the study of the cestodes of fish for about sixteen years—especially in connexion with the Ceylon Pearl Fisheries and as Director of Fisheries in India—and the present volume is the result of that research. This work, supplemented by a recent paper on the Tetrarhynchids (the Tetrarhynchidae is one of the two families composing the Trypanorhyncha) found in Ceylon Marine Fishes (*Ann. Trop. Med. and Paras.*, 1924, 18, pp. 459-491), forms a complete monograph on the cestodes of fish.

This volume consists of four parts, of which the first is of more general interest than the others. It is devoted mostly to a critical examination of the present systems of classification of the whole group. Dr. Southwell believes that the five orders can only be separated naturally by means of the shape of the head. Thus the Cyclophyllidea have four suckers, the Pseudophyllidea either one (rarely) or two (commonly) bothria or sucking grooves, the Tetrephyllidea have four lappet-like outgrowths from the head called bothridia, while the Trypanorhyncha have four proboscides each of which is armed with spines. Forms which cannot be included in any of these four are referred to his new order, the Heterophyllidea. The Cyclophyllidea he proposes dividing into two sub-orders. The first of these, the Univittellata, which is equivalent to Stiles' superfamily Tænioidea, is characterised by the possession of a single unpaired vitelline gland. The second sub-order, the Multivittellata, has more than one yolk-gland and contains the Proteocephalidæ and the Lecanicephalidæ of Bräun. While no system of classification in a subject so imperfectly known as this one can be regarded as permanent, this scheme, even in the light of our present knowledge, is not fully satisfactory. Where in it, for example, can we place the genus *Mesocetoides*? This genus consists of forms with a four-suckered head and a typical Cyclophyllidean anatomy; but the genital opening is ventral, not lateral as in most forms of this order, and there are *two* discrete vitelline glands in a postero-median situation. It does not seem to find a place in Dr. Southwell's scheme. It is so obviously a close relation to the Tænoidean cestodes that it would seem that Dr. Southwell's Univittellata will have to be modified to include it.

The remaining three parts are of interest more to the specialist than to the more general zoologist or parasitologist. Part ii. deals with the Tetrephyllidea, part iii. with the Cyclophyllidea in fish, and part iv. with the Heterophyllidea. These sections, which are illustrated with nearly 250 drawings, discuss in a lucid and exhaustive manner all the forms belonging to these orders found in fish. Apart from the fact that future workers are now provided with modern and comprehensive accounts of these parasites, Dr. Southwell has rendered a very considerable service to science by greatly reducing the number of described species.

The task which Dr. Southwell had set himself was one of great difficulty: the result is a work highly creditable to himself and a contribution of considerable value to zoology.

The volume is introduced by a very characteristic foreword by Sir Arthur Shipley, and forms the second of the series of memoirs being published by the Liverpool School of Tropical Medicine.

The Internal Combustion Engine.

- (1) *Automobile Engines in Theory, Design, Construction, Operation, Testing and Maintenance.* By Arthur W. Judge. (Motor Manuals: a Series for all Motor Owners and Users, vol. 1.) Pp. vii+189. (London: Chapman and Hall, Ltd., 1925.) 4s. net.
- (2) *The Testing of High-Speed Internal Combustion Engines: with Special Reference to Automobile and Aircraft Types and to the Testing of Automobiles.* By Arthur W. Judge. Pp. xvi+392+54 plates. (London: Chapman and Hall, Ltd., 1924.) 25s. net.
- (3) *Cost of Power Production by Internal Combustion Engines.* By G. A. Burls. Pp. iv+56. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1924.) 5s. net.

(1) THERE is something to be said for the point of view that an elementary book on the internal combustion engine should really be an elementary book on the heat engine and should therefore contain an account of the steam engine in addition to those basic principles of the theory of heat which are common to both forms of prime mover. But in practice some differentiation is very usual; the number of readers interested in one is so vastly greater than the number interested in the other. Mr. Judge's book, which appears as one of a series specially written for "all motor users and owners" is an example of this.

We should at one time have expected to find a good proportion of motor owners but ill-equipped for the reading of such a book as Mr. Judge's, but the intense interest taken by a very large section of the public in the technicalities of radio broadcasting shows that we must be prepared to enlarge our ideas as to the receptiveness of the general public to technical writings. If this receptiveness applies now, or can be made to apply hereafter, to the study of automobile engines, Mr. Judge's book should prove to have achieved its object. It contains a great mass of information of the familiar type, and it presents it in a convenient and orderly form. The subject-matter is brought up-to-date; for example, the methods of supercharging automobile and aero engines are described, as are also the features of the modern anti-detonation substances for admixture with ordinary engine fuel.

(2) This book, also from the pen of Mr. Judge, is a very complete statement of the technics of the testing of high-speed internal combustion engines. In the course of its high on four hundred pages, the requirements of manufacturers, of inspectors and of laboratory assistants, appear equally to be met, but it is scarcely a book for general reading: those, however, whose work leads them to consult it will be grateful to the author for the painstaking way in which he has

collected information dealing with every aspect of testing, whether relating to stationary engines, automobile engines, or aircraft power plant.

(3) Mr. Burls is well known as a capable writer on the subject of the internal combustion engine, and we received with interest his new volume on the cost of power production by these engines. The period of time covered by this inquiry, as the author points out, includes that of the War, and many of the figures given are of special interest as showing the rapid increase in costs as hostilities proceeded, and the subsequent slow decline as the world gradually returned towards peaceful conditions. Apart from this, there is the factor that if the interest taken in this engine is to bear fruit, it is necessary that information giving up-to-date figures of capital and working costs, particularly in comparison with other forms of power production, shall be ready to hand. It is rather a shock to notice on p. 44 of this new book that some of the statistics go no later in date than June 1921, although on the same page there is other information dated August 1924.

An especially interesting point is made by the author when dealing with the power capacity of large gas engines. He quotes Sir Dugald Clerk's view of the limiting factor in terms of heat units per cubic foot of piston displacement, and shows that this is much better expressed as a limiting mean effective pressure on the basis of a constant thermal efficiency. As applied to the large gas engine, this leads to the range of 55 to 65 lb. per square inch, and the author quotes 64 lb. as representing current practice in 1924. This makes a bulky installation compared with that of a steam plant, and unless it were for the great difference in the average over-all thermal economy (as 15 per cent. is to, say, 8.5 per cent.) the internal combustion engine would come badly out of such a comparison.

Mr. Burl's book will be of very real use to the engineering profession.

Fossil Man.

Human Origins: a Manual of Prehistory. By Dr. George Grant MacCurdy. Vol. 1: The Old Stone Age and the Dawn of Man and his Arts. Pp. xxxviii + 440. Vol. 2: The New Stone Age and the Ages of Bronze and Iron. Pp. xvi + 516. (New York and London: D. Appleton and Co., 1924) 42s. net.

DURING the past thirty years Dr. MacCurdy has paid frequent visits to the Old World to study on the spot the various discoveries of prehistoric man and his handiwork. For some time he has also directed the American School of Prehistoric Research in Europe. He has taken part in several diggings, notably in the

exploration of the cave of La Combe (Dordogne) by the Peabody Museum of Yale University in 1912. He is curator of anthropology in this museum, and has had much experience in teaching. Dr. MacCurdy is therefore well qualified to produce a students' manual of prehistory with first-hand information, and his two handsome volumes now before us will be widely welcomed. He is cautious—perhaps too cautious—in expressing opinions of his own, but his work is most exhaustive in summarising the conclusions of the authors quoted by him. He has discussed the various subjects with most of these authors, and so is able to present them to the student in the most satisfactory manner.

The first volume begins with a useful glossary, and the second ends with tables of the stratigraphy of palæolithic sites, a repertory of palæolithic art, and a list of the prehistoric monuments of France. Numerous authoritative synoptic tables, besides bibliographies, are also scattered through the text. Dr. MacCurdy has thus provided not only a readable story, with excellent illustrations, but also a work of reference of the greatest value.

After a brief history of the development of prehistoric chronology, there is the usual attempt to correlate the successive races of palæolithic man with the various phases of the ice age which are recognised in the Alps. Late glacial and postglacial time is measured by discoveries in the geology of Scandinavia. The extent of the ice-sheet at the successive periods is shown in a new map which has been compiled from many sources. The handiwork of eolithic and palæolithic man is then treated in several chapters, which are illustrated by photographs of sites taken by the author and by numerous new figures of stone implements in the Yale University collection. Finally, the known remains of the skeleton of palæolithic man are briefly described, with numerous illustrations. Dr. MacCurdy is careful to emphasise the doubts about several specimens of which the antiquity is very uncertain, and he emphatically rejects the discoveries of Ameghino in South America.

A whole chapter is devoted to the Azilian and other stages which belong to the interval between the palæolithic and neolithic periods. Their wide geographical distribution seems surprising when they are tabulated on Dr. MacCurdy's plan. The neolithic period is then concisely treated from every point of view, concluding with an account of the megalithic monuments. There is, however, no allusion to the temples in Malta which have been described as of neolithic age. Fire, hunting, fishing, navigation, the wheel, the domestication of animals and plants, commerce, healing, and magic or religion during the stone

age are then considered in general; and the work concludes with some account of the ages of bronze and iron.

Among the numerous treatises on prehistoric man which have appeared during recent years, the new one of Dr. MacCurdy is assured of a high place, and we cordially recommend it to the notice of all serious students.

Our Bookshelf.

University of London: Francis Galton Laboratory for National Eugenics. Eugenics Laboratory Memoirs, 22: The Treasury of Human Inheritance. Edited by Karl Pearson. Vol 3: *Hereditary Disorders of Bone Development.* Part 1: *Diaphysial Aclasis (Multiple Exostoses), Multiple Enchondromata, Cleido-Cranial Dysostosis*, by Dr. Percy Stocks; with the Assistance of Amy Barrington. Pp. vi + 182 + 16 plates. (Cambridge: At the University Press, 1925.) 45s. net.

OF the twenty-two valuable memoirs issued by the Francis Galton Laboratory for National Eugenics, eight form part of the "Treasury of Human Inheritance." These Treasury memoirs deal exhaustively with inborn anomalies, disorders of growth or pathological conditions, all of which may pass from parent to offspring and therefore afford opportunities of studying the laws of heredity as they affect man. Former memoirs have been devoted to anomalies of the foot and hand, to cleft palate, hare-lip, deaf-mutism, imperfect differentiation of sex, hæmophilia, dwarfism and anomalies of the eye; the memoir under notice, the eighth of the Treasury series, deals with those disorders in the growth of bones known to medical men under the names of *Diaphysial aclasis* (multiple exostoses) and *Cleido-cranial dysostosis*.

The present memoir, for which Dr. Percy Stocks is mainly responsible, maintains the high standard set by former numbers of the series; it will remain for many a day the source from which students and experts must draw information concerning some of the most obscure disorders which overtake the bones of growing children. *Diaphysial aclasis* affects chiefly the growing ends of the long bones. Dr. Stocks has found 976 cases of this disorder in medical literature; 183 families gave rise to 765 cases; there was evidence of heredity in 69.6 per cent. of the cases tabulated. Transmission is stronger through the male than through the female. Another, but rarer, disorder of growing bones is also dealt with, namely, multiple enchondromata, which may be associated with *diaphysial aclasis*, and is certainly related to it in nature. In the condition known as *cleido-cranial dysostosis* there is a partial failure in the formation of the clavicle, and with this there is usually associated an irregular formation of the vault of the skull. Records of 144 cases of this disorder have been collected; the condition was familial in 96 instances.

Prof. Karl Pearson is rendering a most valuable service to all students of the human body by securing the preparation and publication of these memoirs, and it would be a thousand pities if the series were to come to a premature end for lack of public support.

Handbuch der Zoologie: eine Naturgeschichte der Stamme des Tierreiches. Begründet von Prof. Dr. Willy Küenthal. Herausgegeben von Dr. Thilo Krumbach. Erster Band: Protozoa, Porifera, Coelenterata, Mesozoa. Vierte Lieferung. Pp. 513-608. 5.40 gold marks. Fünfte Lieferung. Pp. 609-736. 7.20 gold marks. (Berlin und Leipzig: Walter de Gruyter und Co., 1925.)

THE greater part (pp. 522-686) of these two sections of the *Handbuch* is devoted to an account of the Scyphozoa contributed by Prof. T. Krumbach, of Berlin. He defines the class and gives a short history of the Scyphozoa, in the concluding paragraph of which he refers to the *Tessera princeps* of Haeckel and remarks that this owed its existence to Haeckel's need for a primitive form which, however, never existed in life. The *Tesserantiha connectens* of Haeckel is a larval form of the imperfectly known rhizostome *Leonura*, and a similar larval form is known in the genus *Cassiopea*. The author describes each of the five orders of Scyphozoa, beginning with the *Lucernariida* and ending with the *Rhizostomeæ*, giving under each a definition, a short history, the characters of the principal genera illustrated by schematic diagrams, accounts of the morphology, development, and physiology, references to recorded abnormalities, and brief discussions of the ecology, geographical distribution (with maps), and phylogeny. Appended to each section is a useful bibliography of the order.

Under the order *Coronata* is an excellent account of the strange genus *Tetraplatia*, but the author is careful to point out that there is not sufficient evidence to establish the relationships of this genus.

This is an admirable memoir on the structure, biology, and physiology of the Scyphozoa, and the author is to be congratulated on having brought it, including the references to published works, so well up-to-date—the MS. was closed on December 28, 1924. While the account is well illustrated, there are lacking a few figures which would have been helpful to the reader, e.g. of the remarkable tentaculocysts of *Charybdea* and the tentaculocyst of the adult *Aurelia*.

The remainder of the fifth Lieferung contains a portion of the description of the *Octocorallia* by the late Prof. W. Küenthal—one of the outstanding authorities on this sub-class—and he has given a worthy account of the orders *Alcyonaria* (*Alcyonacea*) and *Gorgonaria* (*Gorgonacea*).

The Subject Index to Periodicals, 1921. Issued by the Library Association. K: Science and Technology. Pp. 126. (London: Grafton and Co., 1924.) 21s. net.

THE Library Association has issued a new instalment of its valuable Subject Index to the periodical literature of science and technology. The section covers the literature published in 1921 but contains some papers of earlier date. There are about 6000 entries obtained from the examination of 290 periodicals.

The periodicals selected are, for the most part, those printed in the English language, being published in the British Empire or in the United States of America. We notice, however, that titles in French and German have been taken from the following periodicals: *Bulletin de la Société pour l'Encouragement de l'Industrie nationale*, *Revue des Deux Mondes*, *Scientia*, *Journal*

Économique, Chemiker-Zeitung, Physikalische Zeitschrift, Sitzungsberichte der Preussischen Akademie, Forschungsarbeiten des Ingenieurwesens, Gewerbeblatt, Zeitschrift des Vereins der Ingenieure, Zeitschrift für historische Waffenkunde, Preussisches Lehrbuch, Zeitschrift für Reproduktionstechnik, and Veröffentlichungen des Militär-Sanitätswesens. This list of foreign periodicals consulted is taken from the first half only of the index which extends to 252 columns, and must not be taken as exhaustive, but it does suggest the question as to whether the Library Association could not see its way to include a greater number of foreign papers in its subject indexes.

The range of subjects catalogued in this section is so wide that any one interested in science will find his own branch of study dealt with under many of the headings, which are arranged in alphabetical order. A few such headings may be quoted as examples: Aeronautics, airships, alloys, aluminium, artillery, atoms, petroleum, relativity, ship propulsion, spectrum, wireless telephones, thermionic valves, vitamins, and parasitic worms. It would be impossible to include every scientific paper published in 1921 without making the list too bulky and too expensive for ordinary subscribers, so that a selection has had to be made.

It will be evident that the compilers of this index must have had great difficulty in deciding what papers should be included and which excluded. We think they have exercised a wise judgment in their selection.

Studies in Ampullaria. By E. G. Alderson. Pp. xx + 102 + 19 plates. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1925.) 21s. net.

THE scope of the work under notice is not what the author originally intended it should be. He had hoped to produce a complete monograph of the genus, but the necessary material could not be got together and Mr. Alderson has unfortunately made use solely of shells in his own possession. This is a very great pity, for the subject even thus restricted has been so ably handled that the wider work would have been warmly welcomed by conchologists—we cannot say malacologists, since all allusions to anatomy and ecology are rigidly excluded.

The author candidly admits that Bolten's name of *Pila* for the genus, or at all events a section thereof, has priority over Lamarck's, and so by the Rules for Zoological Nomenclature should be employed, but seeks to justify his preference by the stale excuse that *Ampullaria* is the more familiar name; thus he misses his chance of assisting in forwarding the cause of uniformity in nomenclature in the sole way in which it can be attained.

The work opens with a full and carefully compiled "Critical Bibliography," which in itself is of great value, but by a strange oversight omits Dall's important proposed classification published in 1904, although one of Dall's names is incidentally referred to later on. Then, after a brief "Introduction," the systematic descriptions of the species follow, each accompanied by a synonymy which seems to have been very thoroughly worked out. Any shortcomings that there may be in a work of this technical character will only reveal themselves to the student who uses it. The nineteen plates of figures, reproduced by half-tone

process from the author's own drawings, are exceedingly good: they are plain, but a limited edition of fifteen coloured copies is announced. The printing and general appearance of the book are admirable.

The Platinum Metals. By Ernest A. Smith. (Pitman's Common Commodities and Industries Series.) Pp. xii + 123. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 3s. net.

MR. ERNEST A. SMITH has produced a useful little work upon platinum and the metals associated with it, though it must be admitted that the latter receive but little, most people will probably say too little, attention. Some of them, such as iridium and palladium, deserve considerably more consideration than the book before us has given to them. Upon the whole the work may be described as accurate, although the author has not availed himself so fully as he might have done of previously published and readily available information. For example, his description of methods used in the Urals for working and washing the platiniferous gravels shows a good many omissions, which a more careful study of existing literature would have avoided.

Interest in platinum has been stimulated greatly within the last few years by the sensational discoveries in the Transvaal, though it cannot be said that the economic importance of these is even now at all known. Mr. Smith's book was written in 1924, and it is therefore no fault of his that it contains nothing more than a casual reference to the occurrence of platinum in the veins in the Waterberg district of the Transvaal. It was only towards the end of 1924 that the discoveries, possibly likely to be fraught with much greater importance, of the occurrence of platinum in the western part of the Lydenburg district were made, and these have only been quite recently described, as for example in two important papers by Dr. P. A. Wagner in the Transactions of the Geological Society of South Africa for 1925, and the *South African Journal of Industries* 1925, respectively. This fact, however, only affords one more illustration of the difficulty of writing any book on a technical subject which shall not be, in some respects at any rate, out-of-date before it issues from the press.

Board of Education. Catalogue of the Collections in the Science Museum, South Kensington; with Descriptive and Historical Notes and Illustrations. (1) Water Transport. 2: Steam Ships of War. Compiled by G. L. Overton. Pp. 102 + 8 plates. (2) Land Transport. 2: Mechanical Road Vehicles. Compiled by E. A. Forward. Pp. 87 + 10 plates (London: H.M. Stationery Office, 1925.) 1s. net each.

(1) THERE are four considerable collections of warship models in London, those at the Imperial War Museum, at Greenwich, at the Science Museum, and at the Royal United Service Institution. The largest and most important is, however, that at the Science Museum. This collection had its birth when the Admiralty in 1864 sent to South Kensington a number of models for the use of the students of the Royal School of Naval Architecture, for though most of these were afterwards transferred to the Royal Naval College, Greenwich, a nucleus remained, and this has been developed from time to time. Of the sailing men-of-war, a catalogue

was issued a year ago, and the catalogue of the steam men-of-war deals with the second part of the naval collections. Compiled by Mr. G. L. Overton, the catalogue shows signs of great care; its illustrations are good, while the historical notes, though brief, are excellent summaries of the progress of warship evolution down to the *Hood*.

(2) The second catalogue under notice deals with the second group of the Land Transport Section of the Museum—mechanical road vehicles. We here meet with the steam carriages of Cugnot, Murdoch, Trevithick, Gurney, and others, as well as the petrol cars of Benz, Panhard, Daimler, and Rolls-Royce. The motor section often has up-to-date bicycles, engines, etc., on loan, but these do not appear in the catalogue. Many of the early historic petrol cars in the possession of the Museum are still stored in the basement.

Biochemistry: a Laboratory Course for Medical Students.

By I. Frost. Pp. ii+56. (Madras: Government Press, 1924.) Not for sale.

THE multiplication of manuals dealing with practical biochemistry for medical students appears to be an expression of the differences existing between the courses in this subject in the various schools. Each teacher selects from the large number of possible exercises those which both fulfil the requirements of the examination his students must pass and at the same time appear to him most suitable. Each school thus tends to develop its own course in biochemistry, with the result that a course which reaches publication as a small manual may fail to meet the requirements of other schools, which are, however, induced by its appearance to publish their own course.

The manual before us appears to us to strike a distinctly original note; Dr. Frost has apparently kept in mind the fact that biochemical investigations nowadays come to the aid of the clinician, and that an acquaintance with the methods used in the laboratory is essential for a true evaluation of the results of these investigations in relation to the clinical findings. The book opens with some experiments on colloids, together with examples of the colorimetric estimation of the hydrogen ion concentration of solutions: the proteins and blood pigments are only briefly treated, but a selection of the modern methods used in the examination of the blood and urine is given, each method being fully described.

We have noted a few misprints, especially on p. 24, where some decimal points have gone astray. Our impression is that the book sets a high standard in biochemistry for the medical student who is not reading for a science degree also.

An Introduction to the Strowger System of Automatic Telephony. By H. H. Harrison. Pp. vii+146. (London: Longmans, Green and Co., 1924.) 7s. 6d. net.

It is not very generally known that the engineers of the British Post Office have begun to change the telephone system of London into a fully automatic one. The task is enormous and it will be fifteen years before it is completed. During part of this time the system will be partly manual and partly automatic, but satisfactory arrangements have now been made so that

this will cause no inconvenience. This book is therefore very timely. It deals exclusively with the Strowger system, which is the one adopted by the Post Office. In this system there is a dial with 10 finger-holes punched in it. If a subscriber wants to call up Gerrard 8830 for example, he has to perform seven operations. He first puts his finger in the digit-hole with a G in it and moves it round to the stop and lets it go. He then repeats the operation with E and R the second and third letters in Gerrard; this connects him to the exchange. He then performs the same operation in the digit-holes marked 8-8-3-0 respectively. This calls up the subscribers. If the line is engaged the usual engaged signal is heard. The causes of delay at present are mainly due to indistinct articulation and to congestion of traffic during the "busy hour." Automatic telephony eliminates the former hindrance and diminishes the latter. As the change-over is effected, the number of telephone girls will be gradually diminished, the exchanges being entirely automatic, but the number of engineers and workmen required will be increased. This book will make a good text-book for class instruction on automatic telephony.

Switchgear for Electric Power Control. By E. Basil Wedmore and Henry Trencham. Pp. xii+335. (London: Oxford University Press, 1924.) 25s. net.

THE electric power engineer will find much in this book that will be of value to him. As electrical stations increase in size, the amount and the cost of the requisite switchgear increase very rapidly. Devices are required for protecting the machines and for protecting the distributing mains. The question often arises whether it is worth while to instal a very expensive protection device in order to protect a main, thus paying a heavy annual insurance, or to run the small risk of having the main broken down. Cable manufacturers naturally favour the latter alternative, whilst manufacturers of protective switchgear favour the former. The authors rightly point out that the psychological device of calling a piece of apparatus a "lightning arrester" alone ensures a market for it, even without the accompaniment of a "publicity campaign." Many English engineers have had the temerity not to use them. It has to be remembered, however, that in Great Britain we rarely have severe thunderstorms. The British Electrical and Allied Industries Research Association is carrying out valuable researches on switchgear, and Mr. Wedmore's official work keeps him in close touch with the most modern developments. The book discusses the latest practice.

Elements of Statistics. By Prof. F. C. Kent. Pp. xi+178. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1924.) 10s. net.

Is it possible to present the elements of statistics in an intelligible form to students almost devoid of mathematical training? The present volume professes to accomplish this, but it does so, if at all, only by an enormous restriction of the scope and depth of the subject. Mere tabulation and pictorial representation of statistics will not in themselves suffice in general unless accompanied by a searching scrutiny of the data,

not merely by applying formulæ to them but also in the light of the principles of the theory of error and of correlation. In the present volume, when a formula is required, it is usually either quoted without proof and used for numerical computation or deduced from one already quoted; but surely the results of such a computation can be appreciated only when examined in relation to the basic assumptions made in deducing the formula. Within the narrow limitations the author has imposed upon himself, the treatment is good and the exposition clear. The book is excellently produced.

Pathologie du sympathique: Essai d'anatomo-physiopathologie clinique. Par Prof. Maxime Laignel-Lavastine. Pp. v + 1080. (Paris: Félix Alcan, 1924.) 90 francs.

THIS volume is an exhaustive thesis dealing with the anatomy, physiology, and clinical aspects of the sympathetic system. Few details are omitted from this ponderous work; indeed, the fault lies in the enthusiasm which tends to implicate the sympathetic system in many conditions of obscure origin. Thus few will agree with the author in associating glaucoma, purpura, and osteodystrophies with sympathetic disturbances. In many instances the evidence in favour of autonomic nervous origin is not sufficiently dealt with; for example, in the section concerning gastric crises in tabes, the rôle played by the vagus is briefly dismissed, and the possibility of "vagal crises" as an entity is not mentioned. It is a pity that such an exhaustive work should have just preceded the valuable contributions of Hunter and Royle; their work on the sympathetic innervation of striped muscle and on treatment by ramisectomy is of course not included. The volume concludes with a very full bibliography.

Les edifices physico-chimiques. Par Dr. Achalme. Tome 3: La molécule minérale. Pp. 350. (Paris: Payot et Cie, 1924.) 20 francs.

THE principal feature of this book is a series of elaborate diagrams, first of the structure of *atoms*, which are represented as aggregates of spheres of various patterns, and then of *molecules*, which are represented as aggregates of these aggregates. The author has thus succeeded in building up a very elaborate series of molecular models; but as the details of these are purely speculative, they are not of any value as an aid to the study of chemistry. On the contrary, the author's system appears to call for a draughtsman to express even the simplest formulæ, and equations which can be written down in a few seconds in ordinary symbols become as complicated as the design of a new pattern for a carpet. It is difficult to see what can follow from such a system except to create a mistaken impression of the complexity of chemical science.

Organisation of Vocational Guidance: a Companion Volume to Administration of Vocational Education. By Arthur F. Payne. Pp. xvi + 438. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 17s. 6d. net.

ALTHOUGH the subject of vocational guidance is as yet in the experimental stage, the literature connected with some of its many aspects is increasing at a very rapid rate—evidence at least of a fairly general interest in it.

This book gives a survey of the chief work done up to the present time and is intended to be of use to all those responsible for advising people about their work in life, and for managers in stores, factories, and workshops. It discusses the various systems of testing intelligence and special aptitudes, normal and abnormal behaviour, physical stigmata, job analysis, as well as the organisation of a vocational guidance bureau. There is a useful bibliography and a large number of charts; it will be a valuable book of reference.

School Geography: a Critical Survey of Present Day Teaching Methods. By E. J. G. Bradford. Pp. 104. (London: Ernest Benn, Ltd., 1925.) 7s. 6d. net.

GEOGRAPHY as taught in schools at the present day shows great advances compared with a generation ago, but Mr. Bradford concludes from a wide experience of teachers and teaching that the tendency is to lay too excessive stress on causal connexions. This results in incoherence and a failure of the pupils to visualise world conditions. While deprecating any return to the mere iteration of facts which of old was the whole content of the subject, he pleads for the need of dwelling on other than causal relationships, especially more insistence on location and quantity. In short, he wants to give more precision and coherence to school geography, and this he believes would increase its educational value. The book is a thoughtful contribution to a difficult problem.

Low Temperature Distillation: Home Oil Supply and the Utilisation of "Waste" Coal. By Sydney H. North and J. B. Garbe. (The Specialists' Series.) Pp. vii + 216. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 15s. net.

THE authors give a reasoned and critical account of the various processes used in the low-temperature distillation of coal. The problem is one of very great importance, and although authorities differ in their estimates of the usefulness and economics of the method, it is certain to attract an increasing share of attention. The present volume may be welcomed as a useful contribution to the literature of the subject. It is well illustrated.

Agitating, Stirring and Kneading Machinery. By Hartland Seymour. (Chemical Engineering Library: Second Series.) Pp. 139. (London: Ernest Benn, Ltd., 1925.) 6s. net.

THE various types of machinery used for mixing liquids and solids are described, but theory has been omitted, "in the belief that this method of treatment will be of more service to the practical chemical engineer." A little theory would perhaps have been found interesting by the general scientific reader, who must feel that the book lies outside his province. It should be useful to those to whom it is addressed, and is well illustrated.

ERRATUM.—By a most regrettable oversight, the notice of the volume "The Atmosphere and its Story," by Ernest Frith, and that of "Why the Weather?" by Dr. Charles Franklin Brooks, were transposed. That appearing in NATURE of August 8, p. 204, refers to Dr. Brooks' book, while the notice in the issue of August 15, p. 241, should have appeared under the bibliographic details of Mr. Frith's book.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Nature of Radiation.

BOTHE and Geiger have recently performed an experiment on the Compton effect (*Die Naturwissenschaften*, 13, p. 440, May 15, 1925; *Zs. f. Phys.*, 32, p. 639, 1925) indicating that the recoil electron, and the photoelectron emitted by the scattered radiation, appear simultaneously. Prof. A. H. Compton has made another experiment (*Proc. Nat. Acad. Sci.*, 11, p. 303, 1925), showing that the direction in which the scattered radiation acts in producing ionisation, and the direction of the recoil electron, are related. The natural interpretation of these experiments is in terms of a corpuscular theory of radiation, in which a corpuscular quantum, glancing off a scattering atom with emission of a recoil electron, very soon hits another atom and emits a photoelectron. This contradicts the suggestion, discussed by Bohr, Kramers, and the writer (*Phil. Mag.*, 47, p. 785, 1924), that there was a virtual field, like the ordinary fields of optical theory, emitted during the stationary states of the atom, the function of which was to induce a probability of transition; for on that view the probabilities of ejection of electrons by the scattering and absorbing atoms would be independent, both being induced by a radiation field existing continuously, and the two electrons would be in general ejected at different times and in unrelated directions. I wish to point out, however, that a corpuscular theory still is not in conflict with the main part of the idea of virtual fields.

The possibility of harmony between a virtual radiation field and a corpuscular structure of light was discussed with great penetration by Prof. Swann, in his address at the meeting of the American Association for the Advancement of Science last Christmas (*Science*, 61, p. 425, 1925). Prof. Swann suggested the existence of a field, obeying Maxwell's equations, the function of which should be to guide corpuscular quanta, which might travel along Poynting's vector. This was also the idea on which the writer was working when he first considered a field emitted during the stationary states, although Prof. Swann was not aware of this. (*NATURE*, 113, p. 307, 1924; *Phys. Rev.*, 25, p. 397, 1925)

The theory in this form was developed in England, under the guidance of Mr. R. H. Fowler, to whom my sincerest thanks are due. The essential feature was the emission of the field before the ejection of the corpuscle; that is, during the stationary state before the transition. By this device were avoided the difficulties of explaining coherence, of the "size of quanta," of the presence of interference phenomena in weak light. When this view was presented to Prof. Bohr and Dr. Kramers, they pointed out that the advantages of this essential feature would be kept, although rejecting the corpuscular theory, by using the field to induce a probability of transition rather than by guiding corpuscular quanta. On reflection, it appeared that no phenomena at that time known demanded the existence of corpuscles. Under their suggestion, I became persuaded that the simplicity of mechanism obtained by rejecting a corpuscular theory more than made up for the loss involved in discarding conservation of energy and rational causation, and the paper already quoted was

written. The changes made in adopting this view were thus not fundamental; it might be mentioned that they were not new, the failure of conservation having been suggested by D. L. Webster and others, and the idea of a field to induce a probability of transition being due to Jeans.

The present experiments, however, seem to show definitely the characteristic properties of corpuscles: the localisation of the active power of a light wave in space (Compton) and in time (Bothe and Geiger), although of course the evidence is as yet meagre. The simplest solution of the radiation problem then seems to be to return to the view of a virtual field to guide corpuscular quanta. One slight difficulty in the way of carrying this out should be mentioned: the velocity of a corpuscle should transform under the Lorentz transformation as a velocity, and Poynting's vector does not so transform. There are other difficulties as well, but one may hope that none of them are insurmountable.

It seems to me of particular value to realise that the facts of optics are, in general, satisfactorily described by theories of the electromagnetic field; that it is highly improbable that any essentially different theory could also explain such an extended set of facts; and that consequently we must expect to find this theory appearing in some form or other in our final description of radiation, whatever that may be, and whether it include corpuscular quanta or not. Some physicists have been tempted to throw away the great work of Maxwell and Lorentz, because there are phenomena which suggest light corpuscles. This seems to me a very doubtful policy; for a corpuscular theory of the kind now indicated would by no means take the place of the electromagnetic theory, but would rather supplement and extend it. Some of the material for this extension must naturally come from such experiments as those of Bothe and Geiger and of Compton.

J. C. SLATER.
Jefferson Physical Laboratory,
Harvard University,
July 25.

The Effect of Diluents on the Initial Stages of Catalytic Action.

It has been long known that the presence of diluent vapours in the reactants depresses the reaction velocity at a catalyst surface. The following quantitative treatment has been confirmed by experiments on the effect of water vapour on the initial stages of the dehydrogenation of alcohol by copper. Let p = the fractional partial pressure of the reactant A , hence $1 - p$ = the fractional partial pressure of the diluent B . Then the rate at which the reactant molecules arrive at the surface is proportional to $p/\sqrt{2\pi MRT} = \mu_A p$, say. Thus the probability that a reactant molecule should bombard a given portion of a catalyst at a given instant is

$$\frac{\mu_A p}{\mu_A p + \mu_B(1 - p)},$$

i.e. the fraction of A molecules in the impinging stream of A and B molecules. According to the conception of Langmuir and Frenkel, a molecule that hits another adsorbed molecule is immediately reflected, whereas when it strikes the bare surface it remains for the short period of time τ . It is also known that chemical action occurs on definite centres on the catalyst surface.

Let n be the number of times one of these centres becomes momentarily vacant in t units of time, then $\mu_A \cdot p \cdot n / \{\mu_A p + \mu_B(1 - p)\}$ molecules of the reactant are adsorbed, and they occupy the portion of activity for a fraction of the total time $= \mu_A \tau \cdot p n / \{\mu_A p + \mu_B(1 - p)\}$.

Similarly for species *B*. If the surface is saturated, the time during which a centre is left vacant is negligible compared with the time it is covered, and

$$t = \frac{\mu_A \tau_A \phi n + \mu_B \tau_B (1 - \phi) n}{\mu_A \phi + \mu_B (1 - \phi)}$$

Thus the fraction of the total time the centre of activity is occupied by the reactant is

$$\frac{\mu_A \tau_A \phi}{\mu_B \tau_B (1 - \phi) + \mu_A \tau_A \phi} = v,$$

and is the fractional reduction in the reaction velocity. Thus

$$1/v = (1 - \lambda) + \lambda/\phi, \quad (1)$$

where $\lambda = \sqrt{\frac{M_A}{M_B}} \cdot \frac{\tau_B}{\tau_A}$ and M_A represents the molecular weight, and τ_A the mean life of the molecule *A* on the surface. This formula may be written

$$(1 - v)/v = \frac{\tau_B}{\tau_A} \cdot \frac{\mu_B (1 - \phi)}{\mu_A \phi},$$

and the fraction $(1 - v)/v$ is the ratio of the number of molecules of *B* to the number of molecules of *A* present on the surface. $\mu_B (1 - \phi)/\mu_A \phi$ is the ratio of the number of molecules of *B* to *A* bombarding the surface $= n_B/n_A$. Thus if n_B/n_A be multiplied by the ratio of the mean lives of molecules *B* to *A* on the surface, we obtain the composition of the adsorbed gas film for saturated surfaces. The composition of the adsorbed gas film in equilibrium with a mixture of gases *A* and *B* is given by

$$\frac{x_A}{x_A + x_B} = \frac{1}{1 + \sqrt{\frac{M_A}{M_B}} \cdot \frac{\tau_B}{\tau_A} \cdot \frac{p_B}{p_A}} \quad (2)$$

These formulæ have been verified for partial pressures of alcohol in water varying from 0.02 to 1.00 times the total pressure.

Fractional Reaction Velocity observed. v .	Calculated from $[1/v = 0.64 + 0.36/p]$.	Fractional partial Pressure of Alcohol in Alcohol Water Mixtures $= p$.
1.00	1.00	1.00
0.94	0.92	0.80
0.83	0.81	0.60
0.60	0.65	0.40
0.40	0.41	0.20
0.22	0.24	0.10
0.10	0.13	0.05
0.05	0.05	0.02

The agreement between the observed and calculated values is within the limits of experimental error.

The apparatus with which these measurements were made has already been described (Proc. Camb. Phil. Soc., vol. 22, pp. 738-50) and is very convenient for obtaining the wide variations in partial pressure necessary.

On the Origin of Species in Flowering Plants.

THE origin of species is the origin of the difference between two species. The existence of a peculiar difference between good species, which does not exist between varieties, has long been realised by systematists and others. This essential difference expresses itself, in part, in flowering plants, in the abortion of pollen and ovules in the hybrids, which

springs, in typical cases: (a) from a different distribution of genes between two or more chromosome pairs; so that vital genes are omitted after the reduction division in some or all of the groups of chromosomes of the F_1 of the cross. An example of this is probably afforded by the crosses of certain species of *Stizolobium* (*Mucuna*) (*Zeitsch. f. ind. Abst. u. Vererb.*, pp. 303-342, 1914), two non-homologous chromosomes appearing to have interchanged genes in one of the species. In the second case (b) the attraction between chromosomes which should be homologous fails in the reduction divisions of the F_1 plant, so that non-conjunction (*Journal of Genetics*, 1925) takes place with regard to one or more pairs. Thus there is an absence of vital chromosomes or the presence of extra chromosomes in some of the pollen and ovules. This is illustrated by the two cannas "Austria" and "Italia," which belong no doubt, as their history states, to the F_1 of species crosses. In "Austria," for example, the 18 single chromosomes show only 1-3 pairs at the reduction divisions. All the other chromosomes segregate at random, so that no more than one pollen-grain or embryo-sac out of thousands contains only the 9 chromosomes from one parent, and survives. In the cross of radish and cabbage, as Karpechenko (*Journal of Genetics*, vol. 14, pp. 375-396, 1924) has lately shown, chromosome conjugation is absent. This has also been shown in certain *Digitalis* crosses.

Hence the origin of species is effected, *inter alia*, by (a) segmental interchange between non-homologous chromosomes, of which some evidence has lately been gathered in *Datura*, and (b) by the loss of attraction between chromosomes which were homologous, producing non-conjunction (*Journal of Genetics*, 1925). The hypothesis of the origin of species from crosses between species in a genus posits the existence of allied species, and can thus only be applicable in more or less exceptional cases.

The species listed, in any genus may consist of forms each showing one or more of the following differences from the nearest allied species:

(1) Mendelian differences in one or more pairs of genes;

(2) Mendelian or other differences permanently sustained by propagation by apogamy;

(3) Shifting of some genes in one species between two or more non-homologous chromosomes;

(4) Loss of mutual attraction between two or more corresponding chromosomes in the two species;

(5) Different chromosome numbers or sizes.

Of course the mere possibility or impossibility of securing an F_1 between two species may often be due to other more superficial causes than these fundamental differences.

The Structure of Benzene and Cyclohexane and their Optical Anisotropy.

IN a recent paper (Roy. Soc. Proc., A, vol. 107, p. 684), I have shown that the optical anisotropy of the gaseous molecules of a number of di-atomic and tri-atomic compounds which is evidenced by the polarisation of the light scattered from them, can be explained by the mutual action of the electrical doublets induced in the different atoms of the molecule by the electric field of the incident radiation. Each atom was assumed to behave isotropically. Satisfactory agreement was obtained between the observed and calculated values of the depolarisation of the scattered light in the case of the molecules CO_2 , N_2O and CS_2 .

The investigation has now been extended to the organic molecules benzene and cyclohexane. Experiment shows that the depolarisation (*i.e.* the ratio of the weak component to the strong) of the light scattered in a direction perpendicular to the incident beam in benzene vapour is 0.067. Assuming that the six carbon atoms in benzene are arranged in a puckered ring as in diamond, with the distance between two neighbouring carbon atoms of 1.5 Å.U., and that the hydrogen atoms are joined to the carbons at the tetrahedral angle at a distance of 1.42 Å.U. (the sum of the "radius" of a carbon atom and half the distance between the optical centres in a hydrogen molecule as calculated from its optical anisotropy), and assuming that the refractivities of the hydrogen and carbon atoms are those appropriate to the respective atoms in the hydrogen molecule and in diamond, the anisotropy comes out to be 2.63:2.63:1. This gives a value of 0.074 for the depolarisation of the transversely scattered light.

If the atoms are assumed to lie in a plane with the carbon atoms arranged as in a graphite ring, the depolarisation comes out to be 0.10. Even in the absence of the hydrogens, the six carbon atoms alone would in this case give rise to a depolarisation of 0.083. If, therefore, we are to retain the plane structure for benzene, it will be necessary to assume that the polarisation of the carbon atoms when the field is perpendicular to the plane of the ring is greater than that when it is parallel to the plane of the ring.

Cyclohexane vapour at pressures less than one atmosphere shows a depolarisation of only 1.1 per cent. This small value is what should be expected from the known structure of cyclohexane. The six extra hydrogen atoms place themselves on opposite sides of the mean plane of the carbon atoms on either side alternately, and the mutual action of the induced doublets causes the average polarisation parallel to the mean plane of the carbon atoms to be diminished while the polarisation perpendicular to the plane is increased, both contributing to a diminution of anisotropy. Calculation on the same lines shows the depolarisation to be expected to be 0.8 per cent.

Magnetic Conditions in Tube Railways.

THOSE who have occasion to make frequent use of the tube railways in London can minimise the monotony of such journeys by taking with them a small pocket compass.

Using one day a pocket compass to determine whether my hurried choice of a train was indeed taking me in the westerly direction I desired, I was astounded to find that this old and valued guide was of two minds, if no more, as to where magnetic north really lay. As the train proceeded, the compass needle oscillated, made a sudden 180° turn and pointed south, and in a few moments reversed its direction again.

Repeated observations show the needle to be scarcely ever steady, and this makes it difficult to distinguish the acceleration effect which must be present: such accelerations when nearly at right angles to the magnetic meridian should produce an angular motion of the needle equal to the angle of change of the "apparent vertical" multiplied by the tangent of the angle of dip. I have noticed motions

of the right sense and of about the right amount, but it has not been possible to compare the amount of the accelerations so indicated with those determined by other methods.

I do not know whether any one else has noticed the complex magnetic condition of tube railways, but I do know that any visitor who relies for directional advice upon a pocket compass may be led sadly astray.

Fine Structure of Optically Excited Spectrum Lines.

IN the course of investigations on the optical excitation of gases in this laboratory, we noticed the interesting fact that the spectrum lines emitted by mercury vapour illuminated by an intense mercury lamp have a much simpler fine structure than usually. For example, the green line 5461, the complexity of which under ordinary conditions is well known, presents no components besides the central line, which when viewed through a 30 cm. Lummer plate, is resolved in 3 components only. The violet line 4359 exhibits the same features, the intensity of the stronger satellites as compared with that of the central line being very much less than in the arc. The same seems also to be true for the yellow line 5770. On the other hand, the lines 4047 and 5791 show all the strong satellites.

This absence of some of the satellites which are intense in the arc affords an argument in favour of the view that these are not due to isotopy.

Science and Intellectual Freedom.

DR. NORMAN R. CAMPBELL (*NATURE*, August 8, p. 208) writes with a certain lack of charity about the numerous men of science, medical men, publicists, and so forth, who have ventured to inform themselves about birth control. To seek knowledge about the origin of species, he informs us, may be honest and honourable, but "knowledge concerning contraception is sought, either from mere prurience, or from intention to practise it or to teach others to do so." But that is just what a Tennessee Fundamentalist would say about interest in evolution. He would say men wanted to know they were beasts in order to make beasts of themselves. It is impossible to let Dr. Campbell's sweeping indictment pass unchallenged. People in general want to know about this matter in order to judge it; they want to know the nature, the naturalness, the physical good or evil of these practices and what the mental and social reactions of this or that line of action may be. It is no more "prurient" to be intelligently interested in the question than in dietary. No one wants the publicly paid medical man to "propagate" this knowledge where it is not desired. But we do want to see him free to give it, cleanly and discreetly, to people who know already that it exists and who will, failing him, probably seek it in shameful and dangerous ways. We object to any sect or section of the community coming with threats of dismissal and injury between him and those who want to know. That is what is done at the present time. And while this is the case in Britain I decline to line up to sneer at the Fundamentalists of Tennessee.

H. G. WELLS.

The Theory of Photographic Sensitivity.

By DR. T. SLATER PRICE, F.R.S., and S. O. RAWLING.

SINCE 1920 our knowledge of the formation of the latent image has been greatly increased by investigations which divide themselves roughly into three chapters. The first notable advance was made by Svedberg during the years 1920-1922, and consisted in the proof that the latent image consists of small centres distributed on the silver halide grains of an exposed photographic plate, the distribution of the centres being entirely according to the law of chance. A grain is not developable unless it contains at least one such centre. The second step was to decide upon the origin of these development centres. Two theories were advanced. In one of these it was assumed that the light itself formed the centres, the grains themselves being supposed to be homogeneous. In the other, it was assumed that there exist in the grains, prior to exposure, nuclei which are not silver halide and which are formed during the manufacture of the emulsion, and that the action of light is to change their condition in such a way that they become centres at which development can start. The first theory was extensively investigated and modified by Silberstein and others in the Research Laboratories of the Eastman Kodak Company, whilst the second was developed by Toy in the laboratories of the British Photographic Research Association. Direct evidence in favour of the second theory was at length obtained by Clark in the latter-named laboratories.

The third advance has recently been concisely summarised by Sheppard (*Jour. Franklin Inst.*, 1925, 200, 51), and deals with the nature of the nuclei postulated in the second theory mentioned above. If the nuclei are light sensitive, and are essentially different from silver bromide, their spectral absorptions should determine the spectral sensitivity of the material, or, at any rate, powerfully affect it. The relative spectral sensitivity of plates before and after desensitising with chromic acid is found to be the same, however, and the distribution of sensitivity corresponds approximately with the absorption spectrum of gelatino-silver bromide (Sheppard, Wightmann, and Trivelli, *Jour. Franklin Inst.*, 1923, 196, 653). Moreover, the experimental relation between the quantity of the incident light energy and the photographic effect produced is just what is to be expected when allowance is made for the light absorption of the silver bromide, the agreement being all the better when the light absorbed is reckoned in quanta (Toy and Edgerton, *Phil. Mag.*, 1924, 48, 947).

As a result of the consideration of the above facts, the following theory of the nature of the nuclei has been arrived at. It is assumed that the action of light is to decompose the silver bromide into bromine and silver, and that the apparent sensitising action of a nucleus or "speck" is confined to increasing its size by accretion of photochemically reduced silver atoms until it is large enough to form a development centre. The mechanism by which this accretion is supposed to be brought about is, apparently, that light is absorbed all over the grain and that the energy of vibration of

the electrons in the atoms of the silver halide crystal is thereby increased; but, as a rule, the transfer of an electron from bromine to silver only occurs in the boundary layer at the surface of the specks. Thus energy flows from the surrounding crystal lattice to the specks where it is released as chemical work, the transfer from distant atoms occurring by radiationless collisions (vibrations) through neighbouring atoms until the edge of the speck is reached. It may be noted that Toy (*Phot. Jour.*, 1921, 61, 420) ascribed to Slade a somewhat similar idea as to the transference of energy within the crystal; at that time, however, the attempt was made to explain on this basis how development centres might be formed by light action without the aid of sensitising specks, the mechanism of the action being a kind of "surging" of energy within the crystal and the consequent formation of development centres where energy sufficient to bring about the necessary chemical decomposition is momentarily concentrated. The new theory may thus be considered to be an extension of Slade's original idea to that of the existence of sensitising specks.

According to Sheppard, the formation of the specks is due to casual adsorption and reaction with the silver bromide of a substance present in the gelatin. The theory given leads to the conclusion that once a speck is formed it tends to increase in size; further, not only will the average number of specks on large grains tend to be greater than on small ones in the same emulsion, but also the average size of speck will be greater. It further follows that the sensitising power of any speck is a function of its size. A large speck would not require so large an amount of chemical decomposition in its neighbourhood as would be required by a small speck in order to make a development centre. Svedberg had already touched on the idea that a certain minimum size of speck is necessary before it can act as a development centre, and Clark had deduced that it must be such that it contains somewhere about 300 atoms of silver.

The theory of the distribution of the specks is therefore in striking agreement with the conclusion arrived at by Toy in 1922 (*Phil. Mag.*, 1922, 44, 368) that there are two reasons why large grains are, on the average, more sensitive than small ones. First, there are more nuclei (specks) present in the larger grains, so that a single grain has a greater chance of having at least one; and secondly, the average sensitivity of the nuclei increases with the size of grain.

There is a third factor which may possibly assist in making large grains more sensitive than small ones. Specks on large grains have a greater volume of silver halide from which the absorbed energy necessary to produce the photographic effect may be drawn.

The investigations which led up to the point marked by the theories outlined above furnish no direct evidence of the chemical nature of the specks. Rapid advances were being made in various laboratories towards the solution of the problem, when a paper of Sheppard, from the Research Laboratories of the Eastman Kodak Company, appeared, in which it is

shown that silver sulphide is a substance which can act as a general sensitiser of the kind described. Sheppard (*Phot. Jour.*, 1925, 65, 380) directs attention to the well-known fact that some gelatins are photographically active, whilst others are relatively inert. Making use of the unrivalled facilities of such an organisation as that of the Eastman Kodak Company, which has its own gelatin manufactory, several thousand gallons of deliming liquor, which is formed in the manufacture of gelatin, and was found to be photographically active, were concentrated by appropriate treatment, active fractions being separated from time to time. Ultimately, after some years of investigation, the active substance was tracked down and identified as allyl isothiocyanate, or allyl mustard oil. In the course of manufacture of a photographic emulsion, this substance reacts with the silver halide grains to give the silver sulphide specks to which reference has been made above. It is estimated that photographically active gelatin contains only about 1 part per 1,000,000 to 1 part per 300,000 of the sensitising substance. Other sulphur compounds have been found to act in a similar manner, a necessary condition seeming to be that the sulphur must be doubly linked

to another atom, and not singly linked to two other atoms. The analogous compounds of selenium and tellurium act in a similar way.

The presence of a speck of silver sulphide in the silver halide crystal would result in a disorientation of the silver and halogen atoms at the common boundary, and consequently give rise to a region of instability in its neighbourhood, a view which is supported by the work of von Hevesey (*Z. physikal. Chemie*, 1922, 101, 337).

In all the work which has contributed to the achievement of the present position in regard to photographic sensitivity, it is remarkable how interwoven the ideas of various investigators have become. A mass of evidence from very different sources has now been accumulated in support of the theory that the high sensitivity of the modern photographic plate is due to the presence, before exposure, of minute traces or specks of some "impurity" on the surface of the silver halide grains in the emulsion. The work of Sheppard is a great step forward and opens up new avenues of research, but much work remains to be done before the problem of photographic sensitivity is finally solved.

Sino-Himalaya.¹

By F. KINGDON WARD.

THAT "Any Man's Land" where China, Tibet, and India meet has come into prominence amongst botanists in recent years by reason of the remarkable wealth of flora discovered there; and connected with the problems of plant distribution which arise is the no less interesting problem of geological structure and history. A brief description of the physiography of this region may serve to illustrate the nature of these problems.

We have as a starting-point the great Himalayan range and the mountainous area of western China. East of the 93rd meridian the Himalayan axis trends towards the north-east. It seems probable that this axis is prolonged across China, and that structurally it could be traced in that direction to the plains.

However, what the traveller, who is unable to follow the strike of the rocks composing a great mountain chain like the Himalaya, sees, is something rather different. He sees the Himalayan range ending abruptly at the gorge of the Tsangpo in the great peak of Namcha Barwa; and even if he recognises the peak of Gyala Peri, which forms with Namcha Barwa the gateway to the gorge, as being on the main Himalayan axis beyond the Tsangpo, he can follow it no farther, for the country is unexplored. From the Tsangpo gorge eastwards he perceives rather a wide breach in the Asiatic divide, beyond which in the complex skein of mountains which form a network over western China he is unable to pick up the dropped thread of the Himalayan axis, though the facts of both animal and plant distribution in eastern Asia point to its former, if not to its continued existence.

That this supposed breach in the Himalayan axis

does really exist seems clear enough; though whether at the eastern extremity or in the middle of the range is not so clear.

Rising on the plateau of Tibet are several great rivers whose sources are far apart and whose mouths ultimately open on different seas; but all of them, rolling down from the highlands, converge on one another, squeeze through a narrow gap flanked by lofty snow peaks, and separate again as they emerge from the mountains. In the west is the Brahmaputra (Tibetan Tsangpo), which, after rounding the great gable end of the Assam Himalaya, swings away to the west. In the extreme east is the Yangtze (Chinese Kin-sha), which, after squeezing through the breach, swings away to the east to cross China. Between them, but closer to the Yangtze than to the Brahmaputra, flow three other big rivers, the Mekong, Salween, and Taron (or eastern branch of the Irrawaddy).

The extreme breadth of this river gap is about 200 miles; but a much smaller distance—namely, 70 miles—will span the gap between the Yangtze and the Taron, including the gorges of the Mekong and Salween. That is to say, these four rivers, where they flow parallel to one another for a depth of about 100 miles, are confined to a strip only 70 miles wide. A further peculiarity about this strip is a pronounced tilt from east to west, whereby these rivers flow at successively lower and lower levels as we proceed westwards from the Yangtze to the Irrawaddy.

The reasons for this may be at least partly explicable on the theory of isostasy, the vast area of deposition towards the head of the Bay of Bengal being counterbalanced by a rise in the country to the east, which is essentially an area of denudation. Even the progressive lowering of the river beds might be due to a detailed isostatic equilibrium, being proportional to their

¹ Substance of two lectures delivered at the Royal Institution on April 3 and 30.

powers of erosion and capacity for deposition, according to the views of Colonel Tandy.²

That the grading of the river beds should follow mechanically from the proportionate rainfall in the gorges seems to us quite untenable. If we accept the view that a river is primarily erosive in action, then the Yangtze, with its much greater and more powerful stream and its larger volume of glacier water, should have cut out the deepest channel; but it has not. On the other hand, if we accept Colonel Tandy's view that a mountain river bed is primarily an area of deposition, then the Yangtze, which certainly receives a much greater dead-weight load from its arid cliffs than does the forested Taron, should still have sunk its bed lower. Moreover, the several source streams of the Irrawaddy show the same progressive decrease in altitude from east to west, though their respective volumes steadily decrease also; and here the rainfall is obviously constant for all.

We must not, however, lose sight of the fact that the breaching of the Himalayan axis was probably due in the first instance to tectonic causes, not to river action; and that therefore the parallel gorges owe their origin at least in part to tension, and follow lines of weakness in the crust. Here again the weight of material which the crust, immediately to the west, has to support, dragging on the folded rocks of the Burma-Yunnan arc to the east, may have cracked the synclines; for the Burma-Yunnan arc is probably of the same age as the main Himalayan uplift.

Prof. J. W. Gregory indeed refers to the Mekong, Yangtze, and other rivers of Chinese Tibet being formed as "tension clefts by the rupture of hard rocks which were pulled apart on the stretched upper side of an arch."³ However, I can deal here only with results, whatever the causes.

The south-west monsoon, blowing up from the Bay of Bengal, strikes against the south face of the Himalaya and drops the bulk of its moisture. Thus it crosses the line of high peaks a comparatively dry wind, and the plateau country behind the Himalaya is in consequence semi-desert.

The Burma-Assam re-entrant, however, forms a funnel-like approach to the Himalayan gap, and the monsoon rushes like a bore through the neck of the funnel and up the river corridors of the Tsangpo, Irrawaddy, and Salween; with the result that the region lying at the head of the gap, and partly behind the Himalaya, is also drenched with rain. Thus the breach, or gap, as we have called it, is the meeting ground of several floras. To the north is the Central Asian flora—more particularly the Tibetan element, pressing southwards through the gap; while to the south is the Indo-Malayan flora, squeezing northwards up the river corridors until it makes contact with the former. In the east is the Chinese or Oriental flora, while confined to the ranges which form a network over the whole area is the Alpine or Himalayan flora.

On the parallel ranges of the Burma-Yunnan arc is found a flora related on one hand to the Chinese flora generally, on the other to the Himalayan flora; and it would appear that these mountains, having received contributions from both the broken ends of the Sino-

Himalayan ranges, have carried this flora far to the south.

Nothing was previously known of the flora round the knee-bend of the Brahmaputra, however, and it was not until 1924 that, through the kind offices of the Indian and Tibetan governments, permission was granted for a botanical expedition, financed by the Royal Society and the Percy Sladen Memorial Fund.

One would naturally suppose that the alpine flora of the Assam Himalaya would more closely resemble that of the Sikkim-Bhutan Himalaya than it does that of the Burma-Yunnan arc; for while the Assam Himalaya stand about midway between Sikkim and Yunnan, the Himalaya form a continuous uplift from Sikkim to Namcha Barwa, whereas the Yunnan ranges are a separate uplift sundered from the Himalaya by several deep river gorges. Yet the reverse was found to be the case.

If we examine the more prolific genera, such as *Rhododendron*, *Primula*, and *Meconopsis*, we find groups common to the Assam Himalaya and to Yunnan which have no representatives in Sikkim. To take a few examples. There exist a group of creeping *Rhododendrons* of the 'Sanguineum' series, previously known only from Yunnan and Burma, now recorded from the Himalaya; they do not extend so far west as Sikkim. Similarly with the undershrub *Rhododendrons* belonging to the 'Saluenense' and 'Campylogynum' series.

Coming next to *Primula*, the section known as 'Sikkimensis' has representatives both in Sikkim and in western China, but hitherto no purple-flowered species was known to occur west of the Mekong; yet such purple-flowered species are abundant in the Assam Himalaya and to the north. Again, the queer *Primulas* which fall into the section 'Maximowiczii' have hitherto been regarded as confined to western China; but two species, possibly identical with the Chinese types, have now turned up in the Assam Himalaya.

Two species of the section 'Dryadifolia,' one of them *P. dryadifolia* itself, hitherto known only from Yunnan, are now definitely recorded as Himalayan, while the 'Nivalis' section, so richly represented in China and so poorly in Sikkim, obtains additional support as a Himalayan group in half-a-dozen species from Namcha Barwa.

In the genus *Meconopsis* we find exactly the same thing—a closer association with Yunnan than with Sikkim. Amongst the 'Grandes,' for example, we find in the Assam Himalaya two yellow-flowered poppies almost exactly like the Chinese *M. integrifolia* and its so-called variety *M. integrifolia* var. *Souliei*; while a species closely allied to *M. impedita* is abundant. The only Sikkim species met with were such as are common to Tibet or to the Himalaya generally, e.g. *M. simplicifolia* and *M. horridula*.

One could multiply examples, but enough has been said to bring out the Sino-Himalayan relationship. I have selected these genera as being those with which, from a horticultural point of view, I am best acquainted; but I believe that when the whole collection has been worked out, this unexpected relationship will be more strongly emphasised. There is also, of course, a considerable endemic flora.

From this it would seem that not only is the present breach between the Himalaya and the Burma-Yunnan

² *Geographical Journal*, May 1921.

³ *Geographical Journal*, March 1923.

arc recent, but that the linking-up of the Assam and Sikkim Himalaya is also recent; otherwise their floras should more closely resemble one another, since they are under almost identical conditions.

The most striking feature of the country immediately to the north of the Tsangpo bend is the number of ice-worn valleys and the extent to which deglaciation has gone on and, judging by the retreating glaciers, is still going on. The Tsangpo valley above the gorge seems to have been in part at least formed by ice action. At all events it is certain that the glaciers of Namcha Barwa once crossed the present valley, since one sees huge amounts of moraine material, continuous with "living" moraines on the right bank, piled up on the north bank, and afterwards cut through and stranded, terrace on terrace, by the river. The gorge itself, however, is clearly due to water erosion, though at one point a glacier does actually reach the river bed from the north bank. This retreat of the ice must be due to gradual desiccation rather than to a general increase of temperature, since lakes are also drying up, and these would scarcely be affected by a small rise of temperature. This ice action is far more conspicuous in the Assam Himalaya and on the ranges to the north of the Tsangpo bend than in other regions we visited;

and it might be that the elevation of the Assam Himalaya is of more recent origin than that of the Himalaya as a whole. If, as Sir Sidney Burrard⁴ has suggested, the Tsangpo originally flowed from east to west, then there must have been much less accumulation of silt in the Assam valley formerly than there is now, with the result that there would be less "compensation" needed. The cutting through of the Himalayan axis by the Dihang and the "capture" of the Tsangpo would soon alter this, and the Assam Himalaya might have been considerably raised as a result. But with the rise of this great rain screen, the doom of the glaciers to the north was also sealed. The removal of this enormous weight of ice, and the consequent transport of a huge amount of abraded material by water to the Bay of Bengal, would still further have loaded the crust in that direction and released it in the Himalayan area.

The numerous considerable falls in the Tsangpo gorge and the steep grade of the bed suggest that this river is much newer than the Salween or the Mekong. Thus the Assam Himalaya might be regarded rather as an outlier of the Burma-Yunnan arc, severed from it by the cutting back of the Brahmaputra (or Dihang), and still bearing a very close resemblance to it in its flora.

⁴ "A Sketch of the Geography and Geology of the Himalaya and Tibet."

Science and Intellectual Freedom.

By WATSON DAVIS and Dr. FRANK THONE, Science Service, Washington, D.C.

AMERICAN men of science naturally felt considerable interest in the trial of John T. Scopes, high school teacher, at Dayton, Tennessee, for the alleged violation of the now famous anti-evolution act on the statute books of that State. Relatively few scientists in this country are directly threatened by the epidemic of anti-evolution legislation; for this is at present confined largely to the southern States, and the majority of the more important colleges and universities, both independent and State-supported, are in the north and west. However, interest in the continued academic independence of their colleagues in the south brought a number of scientists to Dayton as scientific coadjutors for the defence counsel, while many more had signified their willingness to attend if called upon. They would have appeared as expert witnesses also, had the judge not ruled against the admissibility of scientific testimony.

Certain aspects about the outcome of the case may possibly need a word of explanation to those unfamiliar with American law procedure and with the somewhat peculiar circumstances of this particular trial. The defence did not attempt to prove that their client, Mr. Scopes, had not violated the statute as interpreted by the court. They stated that they intended to prove that the law was contrary to the constitution of the State of Tennessee and to the constitution of the United States, and that it was so vague and unscientific in its structure as to be meaningless. For this reason they wished to introduce scientific testimony; and when the court ruled that such testimony was irrelevant, the ground was cut from under their feet. It was conjectured, however, with a good deal of probability, that two or three men on the jury, irritated over the conduct of the case, were prepared to "hang the jury" and prevent the unanimous

verdict necessary to convict. The counsel for the defence wished to prevent such an outcome, for then the case would have had to be tried all over again before another jury, with the outcome just as unpredictable as it was the first time. Therefore we were treated to the unprecedented spectacle of the chief counsel for the defence virtually appealing to the jury to convict his client, so that the case might be carried to a higher court on appeal.

Mr. Scopes was accordingly adjudged "guilty"; and the case will come before the supreme court of the State of Tennessee in September. This tribunal may do one of two things: either decide that the lower court was in error in certain of its rulings and remand the case for re-trial, or declare the statute to be contrary to the constitution of the State. Appeal may also be taken to the United States supreme court, on the ground that the statute is in violation of certain clauses in the Bill of Rights appended to the United States constitution. Of course it is impossible to predict the outcome of either of these appeals.

Certain after-effects of this case have already been making themselves felt. An anti-evolution bill, similar to the Tennessee statute, offered in the Georgia State legislature, was decisively defeated by a viva voce vote. The "fundamentalists" wish to introduce a similar measure at the next session of the national congress, but so far have been unable to find a member willing to sponsor such a bill. An effort to enforce a dead-letter clause in the regulations of the Washington, D.C., schools appears to have gone off as a flash in the pan.

The effort to force an Old Testament theocracy upon the American people will continue, but now that the only champion of the movement who enjoyed national prominence has passed away, his cause will probably dwindle accordingly.

Relativity Displacement of Spectral Lines and Stellar Constitution.

NOT many months ago, a very careful and critical examination by Dr. C. E. St. John of the wave-lengths of the lines in the solar spectrum was sufficient to convince a large body of astronomers that the displacement towards the red of spectrum lines originating in a region of high gravitational potential, required by Einstein's theory of relativity, was an actual phenomenon. An element of doubt remained, however, owing to the exceedingly small amount of the displacement in question and the unknown effects of convection currents and other disturbing influences in the solar atmosphere.

At the time when Dr. St. John's investigation was made, it appeared that no source of light other than the sun could afford a satisfactory test of Einstein's prediction; and that for two reasons. In the first place, the smallness of the displacement to be measured demanded a degree of dispersion and perfection of detail in the spectrum which it was impossible to obtain with the light of any other astronomical body. The relativity displacement depends on the gravitational potential at the surface of a star—that is, on the star's mass divided by its radius—and for no star was this quantity believed to be large enough to give a displacement of more than one or two hundredths of an Ångström unit. In the second place, owing to the identical character of the relativity displacement and the Doppler displacement arising from motion of a source of light away from the observer (both displacements are proportional to the wave-lengths of the lines concerned), it was necessary to select a body the motion of which relative to the earth was known from independent evidence. Since the radial velocities of the stars can be obtained only by means of the Doppler effect, the sun was for this reason also the only body available for the Einstein test.

The restriction thus doubly imposed has now been removed, thanks jointly to some remarkable theoretical predictions by Prof. A. S. Eddington and the extremely fortunate circumstance that Nature has provided a means of testing those predictions. Certain facts of observation recently led Eddington to the conclusion—which he immediately saw to be a natural consequence of his theory of the constitution of the interior of a star—that matter under stellar conditions might attain densities many thousand times greater than those with which we are familiar among terrestrial materials. Not only so, but in the stars known as "white dwarfs," of which two are known, it appeared that these high densities might actually be realised.

These stars are abnormally faint for their spectral type and colour—a fact which suggests that they have very small surface areas and correspondingly large densities; a given spectral type or colour denotes a definite surface brightness per unit area, and an abnormally small total output of light must therefore mean an abnormally small radiating area. Further, the stars are members of binary systems, and their masses can be determined and hence the order of magnitude of their densities. One of the white dwarfs is a companion of Sirius, and therefore one of the nearest of the stars. This fortunate circumstance has just enabled Dr. W. S. Adams of Mount Wilson Observatory (Proc. Nat. Acad. Sci., Vol. 11, No. 7, July 1925) to observe its spectrum in spite of its low intrinsic brightness, and thereby to confirm both Eddington's prediction and the reality of the Einstein gravitational displacement.

The existence of stars having the extraordinary qualities of the white dwarfs removes the necessity of confining the Einstein test to the sun. The extreme compression of the material of the star involves a very high value of the gravitational potential at the surface, and the relativity displacements are of the order of half an Ångström unit. There is therefore no need to use the high dispersion which would be necessary with normal stars. Further, owing to the fact that the star is a companion of Sirius, the space velocity of the two stars must be the same when allowance is made for the orbital motion. All that it is necessary to observe, therefore, is the difference in displacement between the lines of Sirius and those of its companion. This difference, except for the known amount due to orbital motion, must therefore be due to the excess of Einstein displacement in the companion over that in Sirius itself. Working on these lines, Dr. Adams has found almost indubitable evidence of the existence of an Einstein shift of the expected order, and a mean density of the order of 53,000 (water=1).

This remarkable result, which marks a very definite advance in our knowledge of both the foundations of science and the constitution of matter, is interesting on account of the chance which has made it possible as well as for its own intrinsic importance. Had it not been for the fact of the existence of a white dwarf which is, at the same time, one of the nearest of the stars and a member of a binary system of which the other star is a normal one, the confirmation could not have been made.

Current Topics and Events.

IN *Die Naturwissenschaften* of July 17 there appears a report of an address by Prof. Miethe on the production of gold from mercury, from which it seems that, in a mercury vapour lamp operated under suitable conditions, gold actually makes its appearance in amounts amenable to chemical tests. The necessary conditions are rather difficult to define, but with a suitable form of discharge, the gold yield is proportional to the current strength and the time. A definite potential is necessary before

any appreciable quantity is observed. A mercury vapour lamp *in vacuo* is ineffective, but the same discharge in air at atmospheric pressure gives measurable amounts of gold. Again, gold is found after a discharge between two mercury electrodes in paraffin wax, in this case the gold makes its appearance not in the liquid mercury but in the wax along the path of the discharge. In certain experiments even greater quantities of a metal which closely resembles silver are found.

These results are largely confirmed by Prof. Nagaoka's work recently described in *NATURE* of July 18, p. 95. Prof. Miethe attributes the appearance of the gold to the disintegration of mercury atoms under the influence of electronic bombardment. In this report no reference is made to the energetics of the problem, nor is any suggestion given as to the mechanism of disintegration. The author admits that the appearance of silver, if silver it is, as a disintegration product of mercury is certainly not to be expected, although, under suitable energy conditions, the conversion of mercury into gold might be anticipated. In the same issue there is published a letter from Dr. Hönigschmidt giving 197.26 as the atomic weight of the gold thus produced, a value identical with that of ordinary gold. This determination, in conjunction with Dr. F. W. Aston's measurements of the isotopes of mercury reported in a letter to *NATURE* of August 8, p. 208, throws doubt on the transmutation theory.

THE Forestry Commissioners' fifth annual report for the year ending September 30, 1924, shows that steady progress in the work of afforestation in Great Britain has been maintained. During the five years, 1919-1924, the area actually planted by the Forestry Commission was 39,469 acres, of which 37,790 acres were with conifers and 1679 acres with oak, beech, and other hardwoods. In addition, grants made to public bodies and private persons have resulted in the planting (or preparation, with undertaking to plant) of 42,082 acres. The total area planted under the auspices of the Commission was thus 81,551 acres. The Commissioners' planting work is entirely dependent on the timely acquisition of suitable land and on the raising of sufficient young trees in forest nurseries. It is satisfactory then to learn that the Commission has acquired 141,470 acres of plantable land, of which approximately 190,000 acres represent an addition to the existing forest area of Great Britain, the remainder being felled or devastated woodlands. The nurseries established are extensive, and last year's planting of 10,519 acres absorbed more than 22 million young trees. On April 1, 1924, the Crown Woods, aggregating 120,648 acres, were transferred from the Commissioners of Woods and Forests to the Forestry Commissioners, and will be managed on the same principles as estates acquired for afforestation. The sixteen Crown Woods (New Forest, Dean Forest, etc.) and the new areas, thirty-four in England and Wales and twenty-eight in Scotland, where planting on a large scale is being carried on by the Commission, are shown in two maps. The largest of these planting centres is near Thetford in East Anglia; and here a forest of 20,000 acres is in the making. The report gives a full account of the various forestry operations, and is replete with tables and statistics. It has been issued as a Parliamentary Paper (No. 107, price 1s.).

SIR ARTHUR KEITH's description of the fragments of the skull found by Mr. Turville-Petre in a cave near the Lake of Gahlee, which appeared in the *Times* of August 14, confirms the preliminary report that it is to be assigned to the Neanderthal type. It departs

from that type, however, in certain characters in which it appears to approach the type of modern man. Although resembling most closely the Krapina variety of Neanderthal man, the Galilean man differs from that and all other European specimens in having a narrow and high-vaulted skull, and though the eyebrow ridges are massive and strong, the bone enclosing the brain is not thicker than is the rule among modern Europeans. The breadth above the ear-holes is estimated at 120 mm. and the extreme length at 200 mm., while the volume of the brain may be inferred to have been little short of that of the average modern Englishman, which measures about 1480 c.c. A further note by Mr. Turville-Petre suggests that the flint implements represent a transition culture between Acheulean and Mousterian. The predominant types are *coups de poing*, mainly small in size, side-scrapers, trimmed flakes, narrow blades, many retouched along one edge, and small amygdaloid flakes retouched on the upper surface to form Mousterian points. Anthropologists await with much interest the fuller report on the skull, and the account of the excavation of the cave to be given by Sir Arthur Keith and Mr. Turville-Petre to the anthropological section at the forthcoming meeting of the British Association at Southampton.

WE have received from Mr. W. Spencer Lake, 248 Valentine Street, Bendigo, Australia, a letter in which he comments on Prof. Lloyd Morgan's article on "Optical Records and Relativity" (*NATURE*, October 18, 1924, p. 577). In view of the divergence of view with respect to interpretation of *mental reference* to what we speak of as objects of vision, Prof. Lloyd Morgan asked whether it is for the physicist to pronounce judgment. Mr. Spencer Lake is of opinion that though most physicists appear to subscribe to the hypothesis of direct apprehension, yet it is doubtful if many could be found who would assert this unshaken confidence in it. Rather would they admit that they are concerned with sensual images and a "construct-world" formed by them therefrom. It seems to him that the physicist is not called upon to explain to which hypothesis he subscribes because it can in no way affect the physical issue. With regard to the transformations of relativity, they refer not to events in general but to measures and to physical quantities defined by these measures. These measures—spatial and temporal—are arbitrary. They depend upon "local spaces" and "local times." What relativity asserts is that, underlying all points of view and all measures, however arbitrary, there is some element of "invariability," not in the absolute sense, but in the sense that there is something which is independent of point of view, independent of the particular measure-code adopted, and to be regarded as a "law of Nature." The transformations of relativity apply to the quantitative equations by which these laws are expressed. Thus relativity helps to bring us to a better knowledge of the physical world by eliminating what, in our experience, depends upon the local space and time system, for example, the very special space-time frame of classical mechanics. It is not a question of whether the laws

of classical mechanics stand in need of revision or not, but whether the physical world is the same for us as it was before the advent of relativity.

WE have received Vol. I, Part I of the Journal of the Ipswich and District Natural History Society. It will be remembered that this Society was founded on January 1, 1924, as the result of an amalgamation of the Ipswich and District Field Club and the Ipswich Scientific Society. The Society now numbers 250 members, and is divided into six sections, dealing respectively with botany, conchology, agriculture, prehistoric archaeology, microscopy, and photography. The president is Mr. J. Reid Moir, whose address on "The Antiquity of Man in Ipswich" appears as the first communication in the Journal. Other communications deal with the evolution of the river Stour, by Prof. P. H. G. Boswell, the Suffolk and Essex Crag Pits, by Mr. Alfred Bell, Mr. J. Reid Moir, and the late Mr. S. A. Notcutt; and the Suffolk Coast, by Major E. S. Cooper, who traces changes in the coast-line from the earliest times. In view of the importance of the subject we may direct the special attention of students to the paper by Messrs. Bell, Notcutt, and Reid Moir, in which the two former give a list of the crag pits, the types of deposit to be found in each, and directions for reaching them, while the latter deals with the character of the sub-crag detritus beds, and the implements found therein, as well as sites on which each may be best studied.

THE Report of the Board of Visitors appointed by Congress to inquire into the work of the Bureau of Standards at Washington has been issued, and contains much valuable information as to the benefits which have accrued to the United States from the activities of the Bureau. The motor car industry alone has been able to effect economies amounting to 3,000,000*l.* per annum on account of the investigations on fuels, tyres, and brake linings carried out at the Bureau, while the annual grant to the institution has been less than 400,000*l.* The Board emphasises the necessity of more fundamental scientific research, which runs the risk of being given a secondary position in an establishment on which the public makes demands for immediate and profitable returns. A similar point was made by the president of the Société d'Encouragement pour l'Industrie nationale in France in his address at the recent annual meeting, when he spoke of the importance of aiding those who are carrying out research by placing in their hands the instruments they need and the books and periodicals they must read. Owing to the extensive adoption in France of the English Saturday half-holiday, the number of readers who consult the library of the Society on that day has greatly increased.

H.M. STATIONERY OFFICE has of late earned our gratitude by producing many valuable reports in a form that is not merely cheap but also pleasing. Now it has still further marched with the times by placing on sale (price 3*d.*) at the Government Pavilion of the British Empire Exhibition a "Brief Guide to Government Publications," which is as well and

attractively written as any advertisement by a large business house. The section on "Science and Technology" occupies five of the twenty-two pages devoted to a descriptive classification, and that without including archaeology, agriculture, or fisheries. For details the reader is referred to the lists issued by the Departments concerned. It is a pity that the Stationery Office should not feel called upon to mention the numerous and important publications of the British Museum; at any rate it publishes the Annual Return of that establishment. But even as it is, the field to which this pamphlet guides one is astonishing in its extent and variety; few can be familiar with more than a small corner of it.

AN interesting account by Francis Buckley of the glasshouses on the Wear in the eighteenth century appears in the Journal of the Society of Glass Technology for June. Between 1696 and 1737 at least three glasshouses were built on the Wear, probably by a syndicate called the "Company of Glass-Owners at Sunderland." It is interesting to note that the owners either let the glasshouses or, failing that, worked them themselves. About 1741, many glass-makers on the Tyne considered it advisable to acquire the two glasshouses at Sunderland, but the project fell through. The paper contains many interesting extracts from contemporary newspapers.

THE ever-increasing interest in the problem of securing a purer atmosphere with its resulting benefits should receive further impetus from the Conference to be held at the Palace Hotel, Buxton, on October 2-5, under the auspices of the Smoke Abatement League of Great Britain. Practical proposals for reducing both domestic and industrial smoke are being prepared by the League for full consideration by those attending, and prominent individuals have agreed to open discussions at various sessions. It is hoped that a constructive programme of useful work will be initiated, the results of which can be reviewed at the Smoke Abatement Exhibition and Conference at Birmingham in 1926.

DURING Lord Burnham's absence abroad the Duke of Atholl has consented to act as chairman of the Special Appeal Committee of the Imperial College of Tropical Agriculture. The first large donation received since he has "fathered" the Fund is one of 1000*l.* from Messrs. J. and P. Coats, Ltd. This generous gift, following closely upon a contribution of 1000*l.* from the Liverpool Cotton Association, is evidence of the interest which is taken in the Imperial work of the College by the cotton industry. Further contributions from those whose interests lie in tropical agriculture should be sent to Mr. Algernon Aspinall, Secretary, The Imperial College of Tropical Agriculture, 14 Trinity Square, London, E.C.3.

DR. GEZA RÓHEIM, of Budapest, whose reputation as an exponent of the application of psycho-analytic methods in anthropological research has grown steadily since the War, and whose study of Australian totemism on psycho-analytic lines has recently been published in Great Britain, will visit England in the

month of September. During his stay he will read a paper on Hungarian folklore and primitive beliefs at the Royal Anthropological Institute on a date to be announced later. Arrangements are also being made for Dr. Róheim to deliver a course of four lectures on psycho-analysis and primitive religion and magic for the Institute of Psycho-Analysis. Further particulars may be obtained from Mr. John Rickman, the hon. secretary of the Institute of Psycho-Analysis, 26 Devonshire Place, W.1, or at 42 York Terrace, N.W.1. There will be no charge for admission to Dr. Róheim's lecture at the Royal Anthropological Institute, but application for the admission of non-members should be addressed to the hon. secretary, 52 Upper Bedford Place, W.C.1, after September 1.

MR. F. EDWARDS, 83A High Street, Marylebone, W.1, has just issued an interesting catalogue (No. 471) of second-hand books, maps and charts relating to nautical subjects and the South Seas. Nearly 1400 works are listed, some of which are rare. The list can be obtained upon application.

IN catalogue No. 429, Messrs. Bowes and Bowes, Cambridge, offer for sale some 1100 second-hand volumes from the library of the late Dr. F. J. H. Jenkinson, librarian of the University of Cambridge. The books are of a miscellaneous character, but include some dealing with scientific subjects.

MESSRS. W. Heffer and Sons, Ltd., Cambridge, announce for publication in the autumn "Stars and their Uses," by E. B. Leggett, a little volume in verse beginning with an introductory definition of common astronomical terms and proceeding to treat of the earth in its relation to the universe. In

successive chapters it deals with the constellations, circumpolar, zodiacal, and otherwise, and concludes with remarks on the general composition of celestial bodies.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: Two assistants in the department of zoology and comparative anatomy of University College, London, namely, a man, preferably with some training in physiology or chemistry, for an appointment renewable annually, and a man or a woman to take the place of an assistant absent on a year's leave—The Secretary (August 24). An assistant lecturer in the department of pharmacy of the Technical College, Sunderland—The Chief Education Officer, 15 John Street, Sunderland (August 31). A research chemist, a research engineer, and some junior research chemists at the Chemical Laboratory of the Department of Scientific and Industrial Research, Teddington—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (September 4). An assistant lecturer in building construction at the Municipal College of Technology, Manchester—The Registrar (September 25). A senior lecturer in philosophy in the University of Melbourne—The Agent-General for Victoria, Melbourne Place, Strand, W.C.2 (October 15). A temporary engineering assistant in connexion with the Air Ministry—The Secretary (S.I./437), Air Ministry, Adastral House, Kingsway, W.C.2. A junior assistant in the Agriculture Science Bureau of the International Institute of Agriculture—The General Secretary, International Institute of Agriculture, Rome.

Our Astronomical Column.

BORRELLY'S COMET.—A third periodic comet of the six that are due at perihelion in the present year has been found. M. Schaumasse found Borrelly's comet on August 14 at $3^h 18.2^m$ univ. time in R.A. $5^h 4^m 24^s$, N. Decl. $2^\circ 4'$. It was of magnitude 13; the date of perihelion is about October 7.75. The following ephemeris (for 0^h) should be near the truth:

	R.A.	N Decl.
Aug. 22	$5^h 26.5^m$	$3^\circ 57'$
" 30	$5^h 49.0^m$	$5^\circ 56'$
Sept. 7	$6^h 12.0^m$	$7^\circ 58'$

It is a morning object, being on the meridian about $7^h 15^m$.

COMET HUNTING.—Mr. W. Reid, who has been the most successful comet hunter of recent years, contributes an interesting note on his methods to the Journal of the Astronomical Society of South Africa, vol. 1, No. 5. It is particularly seasonable, since there are apparently no systematic workers in this field in the northern hemisphere, so that an amateur would have good prospects of success in it.

Mr. Reid laid down for himself the large programme of sweeping the whole southern hemisphere once a month: he found it advisable to map all the nebulae that might be mistaken for comets. His instrument is a 6-inch Cooke photo-visual equatorial; its definition is very fine, a point that he lays stress upon. He makes north and south sweeps in a fixed hour angle, the diurnal motion sufficing to give a new star field at each successive sweep. One night is devoted to the western sky, another to the eastern. There is

little use in sweeping in moonlight or with bad seeing. He notes that he often sweeps for five hours or more on a good night, and yet his catches average about one per annum, so that the work requires much patience and perseverance, but he notes the sense of intense satisfaction that success brings.

NORMAN LOCKYER OBSERVATORY, SIDMOUTH.—The report of the Director of the Norman Lockyer Observatory, Sidmouth, for the year ended March 31 last, shows that much valuable work has been accomplished during the year. Five papers on various branches of astronomy have been published, and six others are in preparation. The year was, nevertheless, a very unfavourable one with respect to weather conditions, only 133 nights having been sufficiently clear for observations to be possible; of these, all but three were utilised. During the year the first assistant, Mr. W. B. Rimmer, left the Observatory to take up an appointment at the Canberra (Australia) Solar Physics Observatory, and from November 29 onwards the work was conducted entirely by the Director (Dr. W. J. S. Lockyer) and the chief assistant (Mr. D. L. Edwards). The principal work undertaken and completed during the year was the determination of the spectroscopic parallaxes of certain stars and the study of the spectra of some bright-hydrogen-line stars. The accounts show an excess of 73% of expenditure over income, but it is hoped that, by the formation of an endowment fund, the deficiency of assured income below normal expenditure will be considerably reduced.

Research Items.

A LATE BRONZE AGE SITE IN SOUTHERN BAVARIA—The results of an investigation of a site near Istein in Southern Bavaria are described by Dr R. Lais in vol. 24, Pt. 2, of the *Bericht der Naturforschenden Gesellschaft zu Freiburg*. The finds, some of which have an important bearing on the distribution of ceramic ornament in this part of the Central European area in the later Bronze Age, were derived in part from the surface, in part from excavation. Among them were a very fine triangular arrow-head of chert, polished stone axes, stone knives, clay spindle-whorls of double-cone shape and pottery, mostly fragmentary, but of sufficient size to show the character of the ornamentation. The decoration was in the form of rings in relief, incised dots and marks in lines and groups, parallel grooves, zigzags and dog's tooth. It was uniformly geometric with the single exception of a garlanded ornament or series of festoons composed of grooves. In regard to dating, the arrow-head, axes and knives clearly belong to the Neolithic Age, as do the numerous flint-flakes which were found, although some of these would appear to have been used later for the purpose of strike-a-lights. The pottery, however, belongs to a later period and may be an extension of the culture of the Black Forest. It is compared with pottery from an urn-burial at Rheinweiler, 5 km. to the north, and from Aichen, 50 km. to the east. These two finds are to be attributed to the Bronze Age rather than the early Iron Age as has been suggested. The Istein finds may be assigned to the latest phase of the Bronze Age.

ABILITY OF TERMITES TO LIVE ON PURE CELLULOSE.—In his studies on termites, Dr. L. R. Cleveland has shown that through the agency of the protozoa in their alimentary canal, they are able to digest wood and utilise the products. He has kept numerous termites belonging to two genera *Termopsis* and *Reticulitermes* in glass vessels and has fed them for eighteen months on cellulose alone, e.g. filter paper (*Biol. Bulletin*, April 1925). These termites fed on a pure cellulose diet have behaved exactly as the controls fed on wood. Many of the nymphs have become sexually mature adults and have laid a large number of eggs which have hatched normally. Larvæ from these eggs have grown even more rapidly than those from eggs laid by some of the wood-fed controls. In all the experiments the larvæ now present are greater in number and in weight than the individuals present at the beginning, and no deaths have occurred. Some of the colonies which began with ten adult termites now include more than two hundred half-grown individuals. Attempts have been made to determine whether atmospheric nitrogen is being fixed in connexion with the formation of proteins, but no definite result is as yet forthcoming.

THE OVIPOSITION RESPONSE OF INSECTS.—Bulletin 1324 (April 1925) of the U.S. Department of Agriculture is devoted to this subject. Its author, Mr. Charles H. Richardson, discusses the various stimuli which affect the oviposition reaction of insects, giving a large number of references to the literature on the subject. Temperature is an important factor, and within the range of each species of insect there is probably an optimum temperature for egg-laying. Thus, in the case of the Codling moth, oviposition becomes checked at 18.3° C. and was found to cease at 16.7° C. (Isely and Ackerman). Humidity is likewise very important in many but not all species: by increasing the atmospheric moisture from 55 per cent to 96 per cent., egg-laying in *Tomiscus typhographus* was delayed from 1 to 7 days (Hennings). Light stimu-

lates oviposition in the house fly but is without effect on the egg-laying responses of *Drosophila melanogaster* (Adolph). Surface contact is a further factor and often very important: thus, in the webbing clothes moth, investigations by Benedict and by Titschack suggest that the tactile stimulus may be the determining factor regardless of the food value of the material for the future larvæ. Many insects have been found to be attracted by specific odours, but in many cases the nature of the substratum has also to be taken into account in order actually to induce oviposition. The simplest oviposition responses are probably shown by those insects which pass most of their lives associated with substances that serve as food for themselves and their offspring. Most free-living insects, however, require a chain of stimuli to induce normal egg-laying.

PIPERINE AS A MOUNTING MEDIUM—Watson's *Microscope Record* (No. 5, May 1925) contains a useful article by Mr. Chapman Jones, urging the value of piperine as a mounting medium for certain purposes. Its refractive index is 1.68 for the D line, and as it is colourless it is superior to realgar. To avoid crystallisation in permanent mounts, it should be heated to 180° C. for one hour before use, but this is unnecessary for temporary mounts.

TEMPERATURE OF GROUND WATER.—In a pamphlet issued by the United States Geological Survey (Water-Supply Paper 520 F), Mr. W. D. Collins gives a summary, with maps and diagrams, of water available for industrial purposes in the United States. The temperature of ground water is generally from 2° to 3° F. above the mean annual air temperature if the water is between 30 and 60 feet below the surface. At a depth of 10 feet the temperature may range from 10° above to 10° below the mean annual temperature. An approximate average increase may be taken as 1° for every 64 feet. The mean monthly temperature of surface water is generally within a few degrees of the mean monthly air temperature when the latter is above freezing point. In the warmer months the maximum water temperature is usually 2° to 6° higher than the mean monthly water temperature.

ANTARCTIC TERRESTRIAL MAGNETISM.—The first volume of Series B of the Scientific Reports of the Australian Antarctic Expedition of 1911-1914 under the leadership of Sir Douglas Mawson is devoted to terrestrial magnetism. The field observations are dealt with by Mr. E. N. Webb, and Dr. Chree discusses the magnetograph curves. The instruments were lent by the Carnegie Institution of Washington and consisted of two magnetometers, a Dover and a Lloyd-Creak dip circle. Observing stations were established on Macquarie Island, at Cape Denison, Adelie Land, and at Queen Mary Land, and sledge journeys were made along the coast, across Adelie and King George Land, towards the magnetic pole, and across Queen Mary and Kaiser Wilhelm Lands. As a result, the south magnetic pole was found to be at 71° 10' S., 150° 45' E., and the lines of equal dip to be ellipses with their major axes north-west to south-east. The horizontal component of the field was found, partly by the magnetometer, partly by the dip circles, which were provided with deflecting needles. The polar diagrams showing the daily variation of the north and west components are slightly elliptic with their major axes east and west for Adelie Land, while the Scott expedition found them nearly circular for Cape Evans.

WEATHER AT HONG KONG.—An annual summary of the meteorological elements at Hong Kong, with the typhoon tracks in the neighbouring sea and the results of magnetic observations during 1924, are given in the *Monthly Meteorological Bulletin* for December last. The discussion is prepared under the direction of Mr. T. F. Claxton, the Director of the Royal Observatory. No text is given with the voluminous tables, but the latter are prepared with great care and precision. Barometric pressure uncorrected for height above sea-level ranged during the year from 30.31 in. in November to 29.37 in. in July; the highest monthly mean was 30.06 in. in January, and the lowest 29.60 in. in July. Air temperature in the shade ranged from 93° F. in September to 48° F. in January; the highest monthly mean was 82.2° F. in September, the lowest 60.3° F. in February. The total rainfall for the year was 98.57 in., which is nearly 14 inches more than the normal for 40 years; the monthly fall was heaviest in June, but the maximum in an hour was 1.74 in. in May. The brightest month was November with 254 hours of sunshine, and December was the next brightest with 238 hours. The maximum hourly wind velocity was 46 miles in October; the highest in a squall was at the rate of 69 m.p.h., also in October. Two plates are given showing the tracks of typhoons and depressions in the Far East during the year 1924; the tracks very often pass north-eastwards over the neighbouring sea, but others strike inland, passing from east to west in the neighbourhood of Hong Kong. The report of the Royal Observatory, Hong Kong, for 1924, shows that Hong Kong was not visited by a typhoon during the year.

THE DISINTEGRATION OF NITROGEN AND OXYGEN.—The volume of Communications from the Vienna Institute for Radium Research for 1923-24 contains a paper by Dr. G. Kirsch on the disintegration of nitrogen and oxygen by means of swift α particles from radium C. The nitrogen was prepared from the air by absorption, the oxygen from pure potassium permanganate, and the scintillations produced by the products of the disintegration were observed on a zinc sulphide-copper phosphide screen. For nitrogen the expelled α particles have ranges up to 11.4 cm., and the H particles up to about 28 cm. For oxygen the great majority of the α particles have ranges less than 9.3 cm., but there is evidence that for ranges in excess of 9.3 cm., H particles are present in greater abundance than α particles, so that it is not safe at present to conclude that in the disintegration of oxygen H particles are not produced. The author considers that the experimental facts support Pettersson's theory that the α particle causes an explosion of the nucleus, the products moving away in all directions equally, rather than the theory of Rutherford and Chadwick, that the momentum of the α particle is communicated by impact to a portion of the nucleus.

THE RESONANCE LINES OF NEON.—The spectrum of neon in the extreme ultra-violet has been recently investigated by Dr. G. Herz, using a vacuum grating spectrograph (*Zeitschrift für Physik*, June 30). Two strong lines, with the wave-lengths 735.7 ± 0.5 Å.U. and 743.5 ± 0.5 Å.U., have been photographed, the frequency difference between them being 1428 ± 3 cm.⁻¹, which agrees with the difference between Paschen's $1s_2$ and $1s_4$ terms. The two lines are to be regarded as combinations of these two terms with the fundamental term, and are the resonance lines of neon. Paschen had already resolved the spectrum of neon into a complicated system of series; but the term

corresponding to the normal condition of the gas was not determined by him, as these extreme ultra-violet lines had not been observed. The author concludes that the normal state of neon is a p state, and that the inner quantum number to be ascribed to the fundamental term is $J = \frac{1}{2}$ (Lande's notation), or $j = 0$ (Sommerfeld's notation). A provisional value for the magnitude of the fundamental term is 173970 ± 100 cm.⁻¹, but more accurate measurements of the wave-lengths are necessary to obtain a definite value. The paper contains an account of the apparatus made use of in obtaining these results. Owing to the strong absorption of the resonance lines in neon, it was necessary to use a low voltage arc in close proximity to the slit, in a space filled with pure neon at about 4.5 mm. pressure. The light passed through the slit into the spectrograph tube, the pressure of the pure neon in which was about one-thirtieth of this, so that although the light had to pass through a considerable distance to the grating and then to the photographic plate, the absorption was not excessive, and satisfactory photographs of the two lines were obtained. The two ionisation voltages of neon as calculated from these observations are 21.47 and 21.57 volts. This agrees well with the value 21.5 volts measured by Hertz, using the electron collision method.

NITROGEN FIXATION.—The mechanism of the fixation of nitrogen as sodium cyanide has been investigated by E. W. Guernsey and M. S. Sherman, who have published their results in the *Journal of the American Chemical Society* for July 1925. In the process, sodium carbonate and carbon are heated with finely divided iron as catalyst; the equation of the total reaction is $\text{Na}_2\text{CO}_3 + \text{N}_2 + 4\text{C} = 2\text{NaCN} + 3\text{CO}$. It is now shown that the intermediate reactions are (i.) the reduction of sodium carbonate to metallic sodium, (ii.) the formation of sodium carbide from the elements, and (iii.) the absorption of nitrogen by gaseous sodium carbide to form sodium cyanide. Iron has a marked catalytic effect on the absorption of nitrogen by sodium carbide but does not appear to be essential for the reduction of sodium carbonate or for the formation of sodium carbide.

ORGANO-ARSENIC COMPOUNDS.—An account of the chemotherapy of organo-arsenic compounds, by Dr. G. M. Dyson, is published in the *Chemical Age* for July 25. Ehrlich was the first to raise chemotherapy to the level of a science. Three separate aspects of disease treatment attracted his attention, namely, the disappearance of malaria parasites from the blood by the administration of quinine, the decrease of syphilitic symptoms with the use of mercury, and the destruction of various trypanosomes and spirillæ by the use of arsenic compounds. Ehrlich considered some chemical combination occurred between the drug and some specific chemical group in the parasite (receptor group), thus either killing the parasite outright, or preventing it from functioning in an injurious manner (parasitotropism). The most vital problem in the chemotherapy of receptor groupings is that of determining the relationship between chemical constitution of the curative compounds and their pharmacological action on the receptor groups. Working on these lines, Ehrlich discovered the enormous spirillicidal activity of compounds containing the arseno group, $-\text{As}=\text{As}-$. The manufacture of salvarsan, the most important and valuable remedy for syphilis, is described fully. Other arsenic compounds, still more or less in the experimental stage so far as therapeutic action is concerned, are also described.

Southampton Meeting of the British Association.

PROVISIONAL PROGRAMMES OF SECTIONS.

FROM the local arrangements outlined in our issue of August 15, p. 251, and from the provisional programmes of the sections, it is evident that all who attend the Southampton meeting of the British Association will find that the time is very fully occupied. The brief statements below of outstanding features of some sectional programmes, for which we are indebted to the respective recorders, will serve to indicate the fare which is to be set before the members of the Association.

SECTION A (MATHEMATICS AND PHYSICS).

The programme of Section A (Mathematics and Physics) presents some interesting and novel features. Under the presidency of Dr. G. C. Simpson, Director of the Meteorological Office, the subject of meteorology will naturally receive considerable attention, which is in keeping with the great present-day importance of this branch of science.

The business of the Section opens on Thursday, August 27, with a paper by Prof. Orstein of Utrecht, foreign guest of the Association, on the quantum theory of dispersion; he will be followed by several speakers on subjects in spectroscopy. The presidential address on Friday on the new ideas in meteorology will demonstrate the great strides which have been made in the subject in the last decade. The president will be supported by the leading meteorologists in Great Britain, several of whom have promised papers to which the Friday and a portion of the Tuesday sessions will be devoted. On Monday, August 31, there will be a joint discussion with Section C (Geology) on "Variations in Gravitational Force and Direction and its Relation to Geological Structure," a subject upon which a committee of the Section has been working for some time, and upon which many physicists will welcome information because of its considerable industrial import. On Tuesday, September 1 Prof. Appleton will discuss some problems in thermionic valves, and he will be followed by several speakers on allied problems.

An excursion to the Air Ministry Seaplane Station at Calshot has also been arranged.

SECTION B (CHEMISTRY).

One of the features of the meeting of Section B (Chemistry) will be a joint discussion with Section G on the ignition of gases. This will take place on the Friday morning, and will be opened by Prof. H. B. Dixon. Two other discussions have been arranged by Section B, one on Thursday morning, having for its subject surface catalysis, which will be opened by Dr. E. K. Rideal, and the other on Tuesday morning, on the alternating effect in carbon chains, to be opened by Dr. B. Flurscheim.

The presidential address to the Section will be delivered on the Monday morning, when Prof. C. H. Desch will take as his subject "The Chemistry of Solids."

Among other papers of general interest which will be submitted to the Section, mention should be made of a contribution by Prof. E. C. C. Baly entitled "Further Investigations on the Photosynthesis of Naturally-occurring Compounds," a paper by Prof. H. E. Fierz, of Zurich, on "The Liquefaction of Wood and Cellulose and some General Remarks on the Liquefaction of Coal," and a paper by Mr. E. A. Ollard, of the Metropolitan-Vickers Electrical Company, on "The Resistance to Corrosion of Electrodeposited Chromium."

SECTION E (GEOGRAPHY).

Owing to this year's meeting being held in Southampton, the home of the Ordnance Survey, Section E (Geography) will devote special attention to papers on survey and cartography. Col. Com. E. M. Jack will speak on the work of the Ordnance Survey and Captain J. G. Withycombe on its recent productions. Mr. O. G. S. Crawford will deal with archaeology in survey maps. Mr. A. R. Hinks is to devote his presidential address to the science and art of map-making. The relations between geography and anthropology are evident in a paper by Mr. H. Sumner on geography and prehistoric earthworks in the New Forest. The present state of the international map on the scale of 1/1,000,000 is to be described by Major M. N. Macleod, and the question of pronunciation tables for the British sheets by Mr. J. H. Reynolds. In exploration and field work, Prof. J. W. Gregory will discuss the problems of the Queensland Barrier Reef and the most suitable site for boring, while Mr. F. G. Binney will give an illustrated lecture on his recent travels in North-East Land, Spitsbergen. Dr. Vaughan Cornish introduces a new subject in his paper on subjective variations of magnitude in natural scenery. A paper of current interest will be that of Mr. F. J. Richards on the cultural geography of India. Prof. W. M. Hobbs will contribute a paper on the glacial anticyclone.

SECTION F (ECONOMIC SCIENCE AND STATISTICS)

Two matters of great importance at the present time, both to economists and to farmers, are to be discussed in a joint session of the Agriculture and Economic Sections. One is the question of farming costs in relation to farm management, on which a paper is to be read by Mr. J. Wyllie; the other will be raised in a paper by Mr. R. B. Forrester on the marketing of agricultural produce. In the present crisis in British farming these two papers are of especial interest.

At a time, too, when wages problems in our chief industries are pressing for solution, the address of the president, Miss Lynda Grier, on the meaning of wages is equally timely. This paper will be supplemented by one by Mrs. Stocks on the economics of family endowment, and another by Mr. R. F. Harrod dealing with trade crises and the distribution of wealth among the factors producing it. The problem of population is to be considered in two papers, one by Mr. G. F. Shove on the law of diminishing returns in agriculture and its bearing on population, the other by Mr. P. Sargent Florence on "Over Population and the Statisticians."

Two aspects of the financial situation will be considered. Mr. R. G. Hawtrey will deal with the gold standard and the balance of payments, and Mr. P. B. Whale with German finance and the Dawes report. In addition there are papers by Miss I. F. Grant on the enclosure movement and Scottish arable land, by Mr. Fabian von Koch on unemployment relief in Sweden, and by Dr. John Hulme on recent developments in Italy's textile trade.

A new feature this year is the Transport Sub-section. Six papers are to be read, dealing with the technical and economic aspects of transport by railways, roads, canals, and docks.

SECTION G (ENGINEERING).

The president of Section G (Engineering), Sir Archibald Denny, will deliver an address on "Fifty

Years' Evolution in Naval Architecture and Marine Engineering." During this period very remarkable developments have taken place in the construction and equipment of ships, and in this development science and scientific research have played a very important part.

After the presidential address Mr. Edwin R. Mumford will discuss the important question of the comparison between the speeds and powers of models and ships, and after an account of the pioneer work of Dr. William Froude, will show how the method has been applied to solve numerous problems of ship and propeller design; the problem of "cavitation" will also be discussed. Mr. Foster King will trace the development of the scantlings of modern steel ships and show the hindrance to development which resulted from strength calculations not having been used in wood construction. Mr. F. E. Wentworth Shields will describe the quay walls of Southampton, certain of which have been proved unstable owing to the nature of the foundations. He will give the history of the walls and discuss the various remedies adopted to render the walls stable. Mr. W. G. Turner will describe the electric power station at Southampton, and Mr. H. Wauchope will deal with the electric supply and plant of Southampton Docks. Mr. Stanley S. Cook will discuss the efficiencies of steam turbines for marine purposes and the problem of auxiliary machinery and fuel consumption, and Mr. Western Hutchinson will read a paper on "Sailing and Motor Craft, the Scientific Aspects of their Design."

At the joint discussion with Section B (Chemistry) on "Ignition of Gases," Prof. W. T. David will give some account of experiments on the spontaneous ignition of gases and upon the influence of nitrogen and other gases and also infra-red rays upon ignition temperatures and rates of ignition respectively. Mr. C. E. Le Maistre will read a paper on engineering standardisation, and Vice-Admiral Sir Robert Bland Dixon and Mr. T. Berry are to discuss the problem of technical training for naval constructors and engineer officers. Prof. David Ellis will give an account of an investigation into the responsibility of iron bacteria as constructive agents in the formation of incrustation in pipes. In the special case investigated, in spite of every appearance of bacterial responsibility, the incrustation in pipes was found to be due to other causes.

The problem of landslides will be dealt with by Mr. Edgar Morton, and Mr. Oliver E. Simmonds will describe the construction of modern seaplanes. Experimental demonstrations of flow of water in pipes are to be given by Prof. Eustice, and Prof. J. G. Gray is to give demonstrations with the gyroscope. Prof. J. J. Guest is to discuss the dynamics of motor cars. Visits are being arranged to the seaplane station, to Southampton Docks, to an Atlantic liner, to the railway works, aeroplane works, and to Agive oil works.

SECTION H (ANTHROPOLOGY).

In Section H (Anthropology), Dr. T. Ashby in his presidential address will deal with "Engineering in Ancient Rome." In view of his special interest in Romano-British studies, a survey will be made of our present knowledge of Roman Britain in a series of communications dealing with recent excavations in England, Wales, and Scotland. Not only will much of the material of these papers be described here for the first time, but a great deal will be the result of work carried on during the present summer.

In prehistoric archaeology may be mentioned communications by Miss D. A. E. Garrod on the Upper Palaeolithic in Britain; on the Neolithic period by Mr. O. G. S. Crawford, who will deal with changes

of climate and megalithic migrations; by M. Z. le Rouzic on megalithic monuments in Morbihan, France; and by Mr. E. T. Nicolle, who will describe the important Bronze Age mound recently excavated in Jersey. Mr. H. J. E. Peake will raise the question of archaeological distribution maps. Certain aspects of the question of the antiquity of man will be discussed by Sir W. Boyd Dawkins, and Mr. W. P. Pycraft will offer suggestions for a new classification of man. Sir Flinders Petrie's description of recent finds of relics of early man in Egypt is of special interest in view of the correspondence which followed the preliminary announcement of these discoveries in the Press. The Section will also have an opportunity of discussing recent results obtained by the American archaeological expedition to the city of Carthage, which will be described by Mr. Harden.

Other branches of anthropological studies will be well represented, as, for example, by Capt. Pitt-Rivers' account of the natives of the Island of Aua, New Guinea, and their customs and mode of life; and by Capt. Hilton-Simpson's description of the industries of the Shawiya of the Aurès Mountains, Algeria, which will be illustrated by cinematograph films taken by Mr. J. Haseler. Mr. Talbot Rice, a member of the Oxford expedition to Kish in Mesopotamia, will describe the physical characters of the modern Arabs in that area. Some interesting questions relating to heredity in man will be raised by Dr. R. N. Salaman's study of facial types in the Jewish community, which should give rise to a profitable discussion.

Exceptional interest attaches to Mr. Turville-Petre's account of his excavations on behalf of the British School of Archaeology in Jerusalem, in caves near the Lake of Galilee, which have brought to light important evidence bearing on palaeolithic man in Palestine, and Sir Arthur Keith's report on the skull showing affinities with the Neanderthal type discovered there. These communications are the first detailed description of this important discovery to be given in England.

SECTION I (PHYSIOLOGY).

The programme of the Section of Physiology opens with three papers on carbohydrate metabolism, the first of these will be given by Prof. J. J. R. MacLeod, in whose laboratory at Toronto insulin was first prepared, and the second by Dr. C. H. Best, who, together with Dr. Banting, effected the preparation. Prof. MacLeod's communication deals with the carbohydrate metabolism of cold-blooded animals. Dr. C. H. Best will read two short papers on (a) the nature of insulin, (b) the mode of its action. A third paper of considerable interest will be that of Mr. H. P. Marks, who has made some striking observations in relation to the action of the thyroid gland in carbohydrate metabolism. He has found that after prolonged administration of thyroid gland by the mouth to rabbits, a condition ensues in which the injection of sugar produces the same train of severe symptoms as attends the injection of insulin. His results have an important bearing on the cause of the lowered sugar tolerance in hyperthyroidism.

Prof. A. V. Hill, whose work on the mechanism of muscular contraction was rewarded by a share of the Nobel prize for medicine for 1922, will deliver his presidential address on the physiological basis of athletic records on Monday, August 31, and the address will be illustrated by cinematograph. He has analysed the factors limiting muscular effort, and, as a result of observations on the isolated muscle of the frog, has been able to deduce what athletic records should be in man. Work recently carried out in Prof. Hill's laboratory, in which the processes

taking place during continuous activity of the isolated muscle of the frog and of human muscle are directly compared, will be described in a paper by Prof. K. Furusawa on Thursday morning, August 27.

A lecture will be given on Friday afternoon by Mr. J. E. Barnard on the microscopic observation of small bodies. Mr. Barnard's name has, of course, recently been associated with reports of the observation and photographic reproduction by means of ultra-violet light of a cancer virus, the existence of which was demonstrated by Dr. W. E. Gye. The size of some of the bodies has been closely determined and is believed to be 0.072μ , so that Mr. Barnard's achievement is considerable.

On Thursday afternoon there will be a joint discussion with Section D (Zoology) on the functional significance of size, to be opened by Mr. J. B. S. Haldane. On Tuesday morning there will be a joint discussion with Section J (Psychology), to be opened by Prof. T. H. Pear, on the acquisition of muscular skill.

Sectional excursions have been arranged for Monday and Tuesday afternoons, the first to the Anti-Gas School at Tipnor and to the Diving Tank at Portsmouth, and the second to the Fort Grange aerodrome, where some of the tests applied to candidates for the Royal Air Force will be demonstrated.

SECTION J (PSYCHOLOGY).

Differential methods have a prominent place in the programme of Section J at Southampton, where the term "differential" is applied either to a comparison of the reactions to a constant stimulus of two groups differing in one condition, or else to a comparison of the reactions of a group (or two equivalent groups) to two or more different stimuli. Thus a study has been made of special abilities, in arts and science, where "special ability" is meant to apply to a facility developed through special environmental influences and individual interests acting over a number of years and the terms "arts" and "science" stand for the work involved in preparing for first degrees in the corresponding faculties.

Similarly the results of testing physically defective children at the Lord Mayor Treloar Hospital and elsewhere lead to the conclusion that physical defect, if widespread and of sufficiently long duration, produces the symptoms of some degree of amentia; and further, that this mental deficiency resulting from physical defect would appear to be appreciably alleviated by exposure to ultra-violet rays.

In another study, on the discrimination of wool fabrics by the sense of touch, an attempt has been made to define the differences in judgment between members of the wool trade and the consuming public, and the result suggests a method of measuring the wool-trade sense of touch. It is also suggestive of the times that the relationship between buyer and seller is studied psychologically in another paper, where an individual valuation is regarded not as a single price at which the individual concerned will be willing to complete his share of the transaction, but as a whole class of possible prices between which the probability of him completing his share ranges from zero to one.

Our final example is a study of the responses of children when taught by various methods, such as the cinema and oral lessons. The essays written after the various lessons differed in arrangement of material and also in mode of expression or style.

Prof. Spearman will open the sessions with his presidential address on "Mental Law of Diminishing Returns." Two joint discussions will be held, one

with Section L (Educational Science) on "Recent Investigations upon Vocational Guidance," and one with Section I (Physiology) on "The Acquisition of Muscular Skill."

SECTION K (BOTANY).

The presidential address of Prof. Lloyd Williams will deal with the Phaeophyceae and their problems. The investigation of this group of seaweeds has been comparatively neglected, and the conclusions of Prof. Lloyd Williams, who has devoted a life-study to these plants, are looked forward to with keen interest. The study of Algæ will also receive prominence by the communication of several papers on seaweeds.

The only joint discussion in which Section K is participating this year is one with Section E (Geography) on "The Evolution and Colonisation of Tidal Lands," to be opened by Prof. F. W. Oliver, who will speak principally upon the stabilisation of these migrating soils by various types of vegetation. On the geography side, Prof. J. W. Gregory will deal chiefly with the mode of formation of new land areas by the action of the sea. Other speakers in this discussion will be Prof. R. H. Yapp, Dr. Vaughan Cornish, Dr. E. J. Salisbury, and Prof. S. Mangham.

Within Section K there will be a discussion on the interpretation of "Adaptive Characters," which will be opened by Prof. F. O. Bower and contributed to by Prof. J. H. Priestley, Dr. D. H. Scott, and Mr. G. E. Briggs. The argument to be outlined by Prof. Bower will deal principally with certain characters in ferns, to which he has devoted special attention. Prof. Dame Helen Gwynne Vaughan will introduce another discussion on "Deviation from the Normal Course of Sexual Reproduction in Plants," on which Dr. K. Blackburn and Dr. M. Knight also will speak. Recent work has shown that apogamy is of such common occurrence in the plant kingdom that it is time again to take stock of the position.

Most branches of botany will be well represented in other parts of the programme, including physiology, genetics, cytology, plant pathology, morphology, palæobotany and systematic botany.

The popular lecture this year will be given by Dr. D. H. Scott, who will take as his subject "The Transformations of the Plant World in Geological Time." A full programme of excursions has been arranged.

SECTION L (EDUCATIONAL SCIENCE).

On August 27 Section L (Education) opens its annual meeting under the presidency of Dr. W. W. Vaughan, headmaster of Rugby, with a discussion on "The Training of Teachers." Although inspired by the recent Government report, the discussion is expected to include the training of teachers for secondary schools as well as that for elementary school teachers.

Public attention is to be directed to those conditions of boarding-school dietary (institutional feeding), which experience has shown to be necessary for the health of the growing child. It is hoped to arouse general interest in the need for more careful attention to the many factors involved other than those of cost and calorific value of foods.

The disciplinary value of subjects taught in schools is to form the theme of a discussion immediately following the president's address on "The Warp and Woof of Education." Later on in the session a strong attack is to be made on those schemes of school science that do not include the study of living things; the biologist and zoologists are combining to represent the urgent need of a broader basis for science teaching than exists in the majority of schools,

in the circuit or whether it merely serve to attract and hold the determinant, together with the substances the interaction of which it determines. Taking the case of hydrogen and oxygen interacting at a platinum surface, it is open to question whether the platinum be coupled with both gases at adjacent points, the determinant acting as an electrolytic conductor between the two; or whether the determinant be merely adherent to and concentrated upon the platinum, the two gases being attracted to it: thus forming the circuit within which change takes place.

The balance of evidence would seem to be in favour of the former explanation. Thus, platinum influences the interaction of hydrogen and oxygen but not that of carbonic oxide and oxygen. Carbonic oxide and various hydrocarbon vapours even have a protective and preventive action and *apparently* can displace both oxygen and hydrogen from a platinum surface. It might be that carbonic oxide is also more attracted by the liquid determinant. It is almost impossible to grant that any one of the gases can monopolise the surface. The behaviour of carbonic oxide, in fact, is in many respects peculiar and needs special discussion.

Evidence on the point is, perhaps, to be found in recent observations on the interaction of hydrogen and oxygen in presence of silver and gold (D. L. Chapman, J. E. Ramsbottom and G. G. Trotman, Proc. Roy. Soc. A., 197, 92). Bone and Wheeler have shown that both metals are more active after heating in hydrogen but not if heated in oxygen. Chapman and his fellow-workers show that absorbed oxygen acts as an inhibitor, apparently owing to the formation of a film of metallic oxide, whilst absorbed hydrogen does not appreciably diminish or increase the activity of the metal. They have further found that the two gases interact, even at the laboratory temperature, in the presence of a silver film deposited on the inner surface of the vessel in which they are confined. The explanation of the inhibiting effect of the film of oxide may be that, being strongly alkaline, the film holds the *trace of acid* which normally serves as electrolytic determinant. Whether silver act as the catalyst and determine interaction at ordinary temperatures—because it merely attracts the electrolytic determinant and the two gases to its surface—or because either or both of these is absorbed by it, must apparently be left an open question.

The special activity of catalysts, due to their particulate character, may be ascribed to the influence they exercise in maintaining a high "surface concentration" of the interacting substances. On this account, the primary action exercised by the enzyme takes place during the earlier, in fact, a considerable period, at a linear rate, only as the products of change accumulate and the action is reversed to an appreciable extent or the enzyme is neutralised or lamed by products of change is the rate of change perceptibly diminished. This is well illustrated by curves showing how urea is hydrolysed by urease, according as the product of change, ammonia (which but lames the enzyme, as the action is not sensibly reversible), be allowed to accumulate or be neutralised by an acid too weak to affect the enzyme.

Enzymes have a peculiar and rigidly *selective* activity—it is on this account that they form a special class of catalyst. They, therefore, influence the hydrolysis of specific hydrolytes, there is no reason to regard their hydrolytic influence as exercised in any peculiar manner.

To make the argument clear, it may be well to recapitulate and consider the formation of hydrone from hydrogen and oxygen. Being non-conductors, by my postulate above, these gases cannot interact:

By this same postulate, even the presence of "water" would not suffice:

Action would only take place in the presence of an electrolytic determinant.

As, however, the determinant would only be an electrolyte if present as liquid; and moreover, as the formation of liquid appears to be dependent upon the presence of a nucleus, *i.e.* of a surface, it is conceivable that no change would take place unless a catalyst (*k*) were present:

Finally, as interaction takes place in an electrolytic circuit, hydrogen is but indirectly "oxidised" whilst oxygen is hydrogenised

As this illustration shows, oxidation is not a direct but an indirect, *depolarising* effect.

It may be questioned whether water itself, as liquid, should not rank as a catalyst. In the interactions considered, it appears only as part of the electrolytic determinant and is necessarily to be thought of as present in the liquid state. Supposing, however, that in an entirely gaseous mixture—say, under the influence of an electric discharge—a sufficient number of hydrone molecules were temporarily brought into conjunction and formed liquid drops, would these suffice to determine interaction independently of any solid surface? It is possible that they would, if drops were formed under such conditions. The water, however, would not then be acting as catalyst but merely as part of the determinant: the rate of change would not be raised, as it is by solid catalysts.

The argument may be extended to the reverse process—the electrolysis of acidified water between platinum electrodes—and the assumption made that the perhydrone produced during the first stage,

is itself acted upon and hydroxylated during the second:

The "oxoperhydrone" thus formed is then hydrolysed into oxygen and hydrone, being itself acted upon, perhaps, as a composite electrolyte.

If the electromotive force or the current density be increased and the rapidity of attack sufficiently raised, the "oxoperhydrone" may be further hydroxylated:

Ozone may be pictured as formed by the hydrolysis of a "dioxoperhydrone" (also, perhaps, in the form of a composite electrolyte) thus produced:

In like manner, when concentrated solutions, particularly of sulphuric acid, are electrolysed, peracids are formed, which, in turn, according to the conditions, give rise to perhydrone, to oxygen or to ozone when hydrolysed.

Oxidation phenomena in general may be interpreted in a similar manner.

The suspended or inhibited oxidations which Moureu and his fellow-workers have studied so thoroughly in recent years, seem to be consistently accounted for by regarding them as involving the continued backward and forward hydroxylation of competing or antagonistic oxidisable compounds—*i.e.* as interference or reversal effects. I have long thought of the inhibition by hydrogen cyanide of the decomposition of perhydrone by platinum or yeast as due to the formation, in the first instance, of perhydrols and their reversible interaction

In result, the interactions here pictured have the same effect as those postulated by Moureu, the main difference being that the process is more clearly defined, as it is represented as "electrolytic" in all its stages. Moureu has usually assumed that the substance primarily concerned is oxidised to a "peroxide," $A(\text{O}_2)$, from which oxygen is transferred to the inhibitor, a second "peroxide," $B(\text{O})$ being formed, the primary "peroxide" being reduced to another "peroxide," $A(\text{O})$: the original molecules are reproduced by the interaction of these antagonistic "peroxides":

In their recent communication to the Chemical Society, however, Moureu and Dufraisse clearly contemplate the probability that platinum, acting as an oxygen carrier, oxidises the molecules of hydrogen and the interfering gas (H_2 , CO , C_2H_4 , etc.) simultaneously to form two antagonistic peroxides, which then interact, reducing each other.

The oxidation of the two oxidisable substances is and, indeed, must be effected in the same circuit, one of them acting as "depolariser," thereby raising the potential to the necessary extent: otherwise, one would not be oxidised at all or the "antagonism" would be incomplete.

Carbonic oxide may be taken in illustration. I have long wondered at the peculiar behaviour of this gas, in fact since I first read in the early 'seventies Groves' fascinating memoir on his gas battery and Faraday's earlier more complete observations on the combining power of platinum; in the former it is shown that carbonic oxide cannot be coupled with oxygen, as hydrogen can, to form a gas battery. Then came H. B. Dixon's discovery of the incombustibility of the dry gas and the increase in velocity of the explosive wave as the proportion of steam present was raised up to a certain maximum. I have more than once discussed the problem, particularly in 1904, in a brief communication to the Royal Society on "The Retardation of Combustion by Oxygen" (*Proc. Roy. Soc.*, 74, 86), in which I dealt with H. B. Dixon's observations on the retardation of the combustion of hydrogen by "excess" of oxygen and of Bone and Stocking's similar observations on ethane.

Accepting the postulate at the root of the argument in this essay, inasmuch as the oxidation of carbonic oxide is a process involving the electrolysis of water,

action should not take place at a platinum surface, at

ordinary temperatures, because the heat of oxidation of carbonic oxide is below that of hydrogen: the change would be endothermic. Probably, the combustion of carbonic oxide is never a direct effect but is determined by a minute quantity of hydrogen, acting as adjuvant, produced initially when the combustible mixture is inflamed or sparked:

To repeat what I said in 1904, "It is necessary to remember, that whereas both oxygen and water molecules diminish in stability as the temperature rises, the stability of hydrogen peroxide must be at a maximum at a high temperature—since its formation from oxygen and water is an endothermic process. In fact, it is to be supposed that water is readily oxidised at temperatures such as prevail in combustions. If, however, the formation of water be regarded as involving the changes

it follows that water and oxygen will mutually hold each other in check: so that when electrolytic gas is exploded there will be a deficiency of oxygen; as it were, owing to its conversion into hydrogen peroxide, which may be regarded as relatively if not entirely inoperative as an oxidising agent, at high temperatures, in presence of oxygen. On the other hand, when excess of oxygen is present, the water—which is the effective catalyst—will be more or less held back, also in consequence of its oxidation to hydrogen peroxide."

Whether or no the changes pictured above could equally well take place at a cold platinum surface would be open to question, were it not that platinum is known to determine the interaction of hydrogen and oxygen. There is no reason to suppose that carbonic oxide could not enter the circuit of change, as a depolariser, under such conditions. The difference in behaviour at low and high temperatures is, therefore, probably the consequence of differences in the stability of some of the compounds concerned.

As to the form in which carbonic oxide primarily enters into the circuit of change, it is not unlikely

that it is as the hydrol $\text{C}:\text{O} \begin{array}{c} \text{H} \\ \vdots \\ \text{OH} \end{array}$ rather than as

formic acid. Obviously, such a compound would be of low stability and the need of a high proportion of steam, to secure the combustion of carbonic oxide at the maximum rate, may be accounted for by the assumption that the presence of this hydrol, in sufficient proportion, is only to be secured in this way.

The immediate product of the hydroxylation of the hydrol, $\text{C}:\text{O} \begin{array}{c} \text{H} \\ \vdots \\ \text{OH} \end{array}$, would be the "perhydrol"

$\text{C}:\text{O} \begin{array}{c} \text{H} \\ \vdots \\ \text{OH} \end{array}$, a still less stable compound. At ordinary temperatures, at a platinum surface immersed in an atmosphere of hydrogen, carbonic oxide and hydrone, this perhydrol would be antagonised by a corresponding "hydroxyperhydrone" or "oxoperhydrol" and

the two would interact reversibly to their mutual destruction:

At high temperatures, such perhydrols would no longer be formed and the direct combustion of the carbonic oxide with the aid of hydrogen, acting as depolariser, would be effected without their interference and with special readiness.

One other case of apparently anomalous protection against oxidation may be referred to—that afforded by so-called rustless steel and the more recently introduced soft alloy staybrite. The former is a chromium steel, the latter an alloy of iron, nickel and chromium, as free as possible from impurities. That chromic acid will protect iron against oxidation is well known. It may be supposed that, in an alloy of iron with chromium, in which the chromium is properly distributed, both materials undergo surface oxidation to perhydrols, which act reversibly, so that at most a layer of molecular thickness is affected, a coating being formed which may well correspond with the (?) unimolecular layer of oxide upon the surface of the far more sensitive metal aluminium.

It is permissible to suggest that the influence of certain dyestuffs in checking the "fogging" of an undeveloped photographic plate may perhaps be traceable to the initial production of antagonistic perhydrols by simultaneous hydroxylation of the sensitive film and the coloured material.

Finally, some reference to the oxidases may not be out of place. These are commonly spoken of as enzymes but they are in no way comparable with

these, in so far as they act selectively. They are only selective in the broad sense, that they are effective agents in determining the oxidation of compounds of a particular general type. Thus so-called tyrosinase will determine the oxidation of phenolic compounds of a certain type—not of tyrosin alone. This is true of "oxidising" organisms, such as *Bacterium aceti* and *B. xylinum*. The behaviour of *B. aceti* is altogether peculiar—although active towards ethylic and normal propylic alcohols, it has no action upon either methylic or isopropylic alcohol. At present we know so little of the process at work that it is impossible to attempt any precise explanation of these peculiarities. It may be suggested, however, that they are traceable both to configurational and energy differences in the systems concerned; moreover, it is clear that something more than the simple, direct oxidation of the alcohol is to be contemplated and that cross-interactions may be at work. Maybe we shall have little success in interpreting such actions until we no longer think "on paper" but have clear conceptions of the solid configuration of molecules. The oxidases may well be discarded from the class of enzymes and regarded as simple catalysts—of a parity with platinum black.

Not a few mysterious processes may be open to interpretation in accordance with the principle developed in this essay. The peculiar behaviour of phosphorus is a case in point—especially the dependence of the appearance of luminosity upon the partial pressure of the oxygen and the phenomena of intermittent luminosity to which Lord Rayleigh has recently directed attention. Little can be said with advantage, however, until we know far more of the several stages of the oxidation process—which may well be as complex as that of the interaction of nitric acid and metals.

Genetical Investigations.

THE practical value of chromosome studies is perhaps nowhere better demonstrated than in the wheats, where the species belonging in different groups have different multiples of 7 as their chromosome number. In hybrids between species with different numbers of chromosomes, the peculiarities in the hybrid behaviour are largely explained by the history of the chromosomes, some of which pair in meiosis while others remain single.

Sax and Gaines¹ draw several conclusions from a study of hybrids between emmer wheats (28 chromosomes) and vulgare wheats (42 chromosomes), which have been grown through several generations. The various segregates tend ultimately to have the same chromosome numbers as the original parents. This is accomplished through sterility or loss of chromosomes in forms with intermediate numbers, as has been found also in the *Enotheras* and in other cases. Segregates with 28 chromosomes resemble the emmer wheats, while those with 42 have most of the vulgare characters. This indicates that the 7 extra pairs of chromosomes determine most of the vulgare characters. The chromosome behaviour would lead to the expectation that ordinary Mendelian segregation would occur in characters, such as presence or absence of awns, yellow or black awns, and red or white grain, which are common to both the emmer and vulgare groups of wheats; while aberrant segregation would occur in regard to characters which distinguish the two groups. This is largely borne out by the

results of experiment. Some of the segregates show combinations of typical emmer and vulgare characters, which indicates that the 7 unpaired chromosomes (which are irregularly distributed in meiosis) independently determine particular characters of the vulgare group.

Another interesting result, obtained by Mr. and Mrs. Sax,² is derived from a cross between *Ægilops cylindrica*, a grass found in Italy, the Balkans, and neighbouring countries, and Marquis wheat, one of the most productive varieties of *Triticum vulgare*. *Ægilops*, like the emmer wheats, is tetraploid, having 28 chromosomes. The F₁ hybrid with *T. vulgare* is pentaploid (35), but unlike the crosses between tetraploid and hexaploid wheats, there are only 6 or 7 bivalents in meiosis (instead of 14), the remaining 21 chromosomes remaining univalent or unpaired. Nevertheless, the tetrad divisions are run through with very few irregularities, some of the univalent chromosomes apparently dividing in the first meiotic division while others divide in the second. The F₁ hybrids are in general intermediate between the parents, and are almost but not completely sterile.

The authors point out that this species of *Ægilops* and another both contain all the characters which distinguish the vulgare from the emmer wheats, and they suggest that the hexaploid vulgare wheats may have arisen through a spontaneous cross between *Ægilops* and a tetraploid (emmer) wheat. Irregular distribution of the unpaired chromosomes, of which there would probably be 14, would occasionally

¹ Sax, Karl, and Gaines, E. F., 1924, "A Genetic and Cytological Study of certain Hybrids of Wheat Species," *Journ. Agric. Research*, 28: 1017-1032, pls. 2.

² Sax, K. and H. J., 1924, "Chromosome Behaviour in a Genus Cross," *Genetics*, 9: 454-464, pls. 2.

produce a gamete with 21 chromosomes. The union of two such gametes, if the chromosomes were balanced in qualities as well as in numbers, might have produced the first of the hexaploid wheats. Thus is crossing combined with chromosome aberrations made the basis for a theory of the origin of our cultivated wheats.

Contributions continue to be made to the study of size inheritance. The prevalent interpretation is that size in organisms and in their parts is controlled by cumulative polymeric size factors the various increments of which give the appearance of a continuous series. Much evidence is appearing in favour of this view. Sax³ has recently, from experiments with beans, found evidence of linkage between certain seed-coat colour patterns and certain factors for size of seed. Cases have even been found in which a factor for large size was contributed by the small parent. Such a result might occur if the small parent contained a few factors for large in addition to a number which made for small size.

Closely related to size-inheritance are the problems of shape. The work with animals indicates that some size factors may affect the body as a whole while others independently determine the size of particular organs. These conceptions have already been applied by Davenport to man, and in a recent contribution⁴ he considers the inheritance of body build. He recognises five classes of build, ranging from very slender to very fleshy. Two slender individuals usually have only slender children, while the progeny of fleshy individuals are much more variable. Such data lead again to the hypothesis of multiple factors, and it is believed that in some families so many as three genetic factors for increasing fleshiness are present. These factors are thought of as influencing size by the effect they have upon the activity of the thyroid, pituitary, and other endocrine glands.

Similar conceptions are being applied by Frets, Hildén, and others to the inheritance of head-shape. Thus it appears that several factors for broader head may change a dolichocephalic to a brachycephalic skull. Thus genetics is destined to have a fundamental effect upon the interpretations of anthropologists.

R. RUGGLES GATES.

The Carbonisation of Coal.

THE Chemical Engineering Group of the Society of Chemical Industry met on July 16 at the forty-fourth annual meeting of the Society at Leeds. Three important papers on features of coal carbonisation were read before a crowded audience, and the discussion had to be adjourned to another session proposed to be held in Leeds in the autumn. Solid fuels were dealt with in two papers: "Smokeless Fuels—the Present and Future Possibilities," by C. H. Lander and Margaret Fishenden, and "Solid Smokeless Fuels," by E. C. Evans. In the former paper the British fuel situation was analysed, particularly with the view of estimating the possibility of establishing new carbonising industries. If all coal were to be pre-carbonised, the disposal of gas and tar would become considerable problems. If domestic fuel only were to be carbonised, this difficulty would be much less, but it was considered that a coke of much more suitable character than that currently produced in gas works would be required. The domestic fuel market is the most promising outlet for carbonised

fuel of suitable character. It was concluded that the most suitable carbonisation process to meet this need cannot be defined with certainty. The solution of the problem may prove to be not in any single method of carbonisation but in several, each operating in circumstances most favourable to its requirements.

E. C. Evans gave a classification of smokeless fuels, directing attention to the properties of anthracite, for which there is a steady demand even to-day, in spite of its high price. This points a moral to those desirous of introducing carbonised domestic fuel. Gas coke he considered as far short of the ideal, particularly because of its high ash and moisture content. The reactivity of coke was treated at length, and the factors influencing it were analysed. Methods of low temperature carbonisation were discussed. In summing up, Evans thinks that low and high temperature systems are approaching one another, and that ultimately a compromise will establish itself. In the discussion it was significant that, in so representative an assembly of fuel technologists, no one could be found to assert confidently the commercial feasibility of existing methods of low temperature carbonisation which figures so prominently in the Press and on the platform.

F. S. Sinnatt and J. G. King brought forward a study of the tars and oils from coal. From an analysis of the economics of mineral oils and coal tars, they drew the conclusion that the prices obtainable for low temperature tars would, so far as present promise goes, be low and liable to great fluctuation. The calorific value of such tar is low, and the difficult miscibility with mineral fuel oil is a limitation. This is not necessarily fatal, for the Lessing process for separating the pitch-giving constituents, now under trial at the Fuel Research Station, shows considerable promise. Some account of these results was given. The limited knowledge of the chemistry of low temperature tar was emphasised, and it was suggested that organic chemists should take up the study of its properties. The production of liquid fuel from coal, either by hydrogenation of the coal or of the gasified product, was also discussed.

University and Educational Intelligence.

"INFORMATION regarding courses and careers open to students of science" proposing to enter the Faculty of Science of the University College, Cardiff, is given in a little pamphlet issued this year for the first time by the College authorities. It follows the lines of the similar pamphlet issued by the University of Birmingham last year and represents a commendable anxiety on the part of the College to acquaint parents, guardians, and heads of schools with the opportunities it offers, so that the last year or two at school of those intending to go on to college may be utilised to the best advantage.

FROM the Royal Technical College, Glasgow, and the Merchant Venturers' Technical College, Bristol, we have received prospectuses for 1925-26. The former, which is the only institution in Great Britain providing regular courses in the technology of sugar manufacture, announces that to meet the requirements of the beet sugar industry, the lectures in this subject will begin in January and will extend over the summer session. Both Colleges give lists of the engineering firms which offer facilities to students for acquiring practical experience in their works. The Merchant Venturers' College offer, as alternative courses for the degree of B.Sc. in engineering, a

³ Sax, K, 1924, "The Nature of Size Inheritance," *Proc. Nat. Acad. Sci.*, 10, 224-227.

⁴ Davenport, C. B., 1925, "Body-build: its Development and Inheritance," *Eugenics Record Office, Bull. No. 24*, pp 42, figs. 25.

continuous 3-years' course, a 5-years' course of evening class work, and the Bristol sandwich system, which interposes practical training in a works for 14 months between the first and second sessions of academic work, for two summer months between the second and third sessions, and finishes with practical work for 14 months after the third session. Loughborough College, on the other hand, claims in its Calendar for 1925-26 to have found a better way of training by providing facilities for all necessary practical work in its own workshops, so that the theoretical work in the College may be made to keep step with the workshop training.

HONOURS courses in American universities and colleges are described by President Aydelotte of Swarthmore College, Pennsylvania, in a report recently published (Bulletin No. 52 of April 1925) by the National Research Council of America. So vigorous is the movement in the United States for liberalising higher education by the introduction of honours courses more or less like those open to students in English universities, that the number of institutions offering such honours work has doubled since the publication in January 1924 of the first edition of this report, when the number was about 46. The character of the movement is determined by the recognition of two principles which are regarded as the foundation of the success of the English honours system: the frank distinction between students who are really interested in the intellectual life and those who are not, and the recognition of the necessity of allowing the former more responsibility for working out their own intellectual salvation. President Aydelotte is careful to point out in concluding his report that "the system now being introduced need not mean any curtailment of the quality of teaching enjoyed by the average student. What our best students need is not coddling, not more attention, not more teaching, but only greater freedom and more severe requirements."

In the report for the session 1923-24 of the Department of Coal Gas and Fuel Industries of the University of Leeds, the Livesey professor remarks that whilst the Department is developing satisfactorily so far as post-graduate work is concerned, the supply of students taking the normal three or four years' course of training in fuel, leading to a degree or diploma granted by the University, is inadequate to meet the demands of the fuel industries for trained fuel technologists. The University requires a steady supply of students, whose numbers may be depended upon from year to year, rather than any large increase in their number. Laboratory facilities at the disposal of the Department are at present inadequate to enable students of mechanical, civil, and electrical engineering to obtain desirable training in fuel technology and metallurgy. Through the generosity of Mr. Henry Woodall, and a number of gas companies and other industrial concerns, an experimental coal gas plant has been presented to the University, and has been employed in work carried out for the Gas Investigation Committee of the University and the Institution of Gas Engineers. Research work carried out in the Department relates to the influence of ash constituents in coal on the carbonisation process; the scaling of metals; the hardness of metals as affected by grain size; the transformation of quartz during the process of manufacture of silica bricks; metallic coatings resistant to oxidation at high temperatures; gas purification; the thermal expansion of metals and alloys and the changes occurring on heating clays, bauxites, etc.; the aeration of gas jets, and heat recovery by waste-heat boilers

Early Science at Oxford.

August 26, 1684. Dr. Plot, lately come from ye Royall Society, informes us, that in a meeting of that Society, on some day in this month, he saw a handkercheif, made of Salamanders Wool, or *Linum Asbesti*, shewn ye Royall Society by a merchant, who lately brought it from China. To try whether it was genuin, or no, it was put into a strong charcoal fire; in which not being injured, it was taken out, oiled, and put in again; ye oil being burnt off, the handkercheif was taken out again, and was altered onely in two respects; it lost two drachms and five grains of its weight, and was (as ye merchant affirmed) more brittle then ordinary; for which reason, it was not handled untill it was grown cold, by which time it had recovered its former tenacity, and in a great measure its weight.

The merchant, who oblidged ye Society with ye sight of so great a Rarity, acquainted them, that he received it from a Tartar, who told him, that the Tartars, among whom this sort of cloth is sold at £80 sterling for a China Ell, (which is less than our Ell,) use this cloth in burning ye bodyes (to preserve ye ashes) of great persons, and that in Tartary it is said to be made of ye root of a tree. The thread of it was (as ye Doctor affirms) very large.

He also acquainted us, that it haveing formerly been queried in ye Royal Society in London, whether ye Air contained in ye spirit within a thermometer, be not some cause of the ascent of that spirit in hot weather.

This quære was resolv'd by ye following experiment: a little Siphon was made to reach from ye top of the thermometer, to the receiver of Mr. Boyl's pump; ye air in the thermometer was drawn out, after which a warm hand being applied to it ye spirit did *still* rise.

The observations of Mr. Bullialdus, Mr. Cassini, and Mr. Jacobs at Lisbon concerning ye last solar Eclipse, were presented our Society, and compared with those made here at Oxon.; and at Greenwich.

Mr. Boyle's booke of ye Porosity of Bodyes was communicated to our Society.

A Letter from Mr. Robert Spear to Dr. Wallis, dated from Port Royall in Jamaica, May 10, 1684, was read; it mention'd a Booke lately printed at Boston, in New England, entituled *An Essay for the Recording of Illustrious Providences*; in which, among other relations, there is an account of ye poles of some needles of Sea-compasses being burn'd by thunder, and lightning, near New England; it is almost verbatim with the account of the same thing mention'd in ye Philosophical Transactions no: 157.

Dr. Plot shewed us some of ye *Risagone Ind.*; or Cassumminiar, a root found on ye mountains 24 gr. Lat: about Patmia near Bengal. Snow will not lye over it long; 'tis of very thin parts, bound up in an earthy matter; us'd in many diseases of ye head and nerves, and in dysenteries; being ground to powder, and given in common water; a decoction of it is made in ye same manner as coffee.

The Doctor tells us, as he is inform'd by good hands, that Mr. Hugh Percy of Weymouth has enquired into ye nature of ye current at ye Straights mouth, by letting fall a bucket, and a weight with it, and that he found his bucket constantly carried outwards; it is to be wished that Mr. Percy be desired to give his own account of what he has done in this kind.

September 2, 1684. There being no great appearance of company, all business was deferred to some fuller meeting.

Societies and Academies.

CALCUTTA.

Asiatic Society of Bengal, July 6.—Braja Lal Mukherjee: The Vratyas and their sacrifices. Vratyastoma is a social or religious penance for those who have in some manner or other defied or neglected religious law and order. Men originally belonging to the Vaidik community, but becoming alienated, and neglecting or defying Vaidik precepts, and creating disorder, were called Vratyas.—Bimala Charan Law: Data from the Sumangalavilāsini. An attempt has been made to present from the Sumangalavilāsini (the commentary on the Dīgha Nikāya of the Sutta Piṭaka, written by Buddhaghosa), interesting materials for the study of ancient Indian life.

SYDNEY.

Linnean Society of New South Wales, May 27.—May M. Williams: Contribution to the cytology and phylogeny of the siphonaceous Algæ. (1.) The cytology of the gametangia of *Codium tomentosum*. In the nuclear divisions occurring in the cœnocyctic threads of the vegetative parts of the plant, twenty univalent chromosomes are present. Reduction division occurs in the gametangium as the result of two nuclear divisions which occur there. Certain of the nuclei present in the young gametangium degenerate before these divisions occur. The selection of functional nuclei is associated with the presence of bodies of the nature of cœnocentra within the gametangium.—H. Burrell: Burrowing habits of *Ornithorhynchus*. A Platypus (usually the female), in excavating its burrow, will, if necessary, lie on its back to work. Its muscular and mobile movements are described, particularly with reference to the work of the hind feet, which have a "two-way" action, and are as versatile as those of a chimpanzee. The functions of the hind and front legs are interchangeable.—J. R. Malloch: Notes on Australian Diptera. No. vi.—G. D. Osborne: Geology and petrography of the Clarencetown-Paterson District. Part iv. The petrographical account of the Kuttung igneous rocks is divided into (a) a general discussion of such matters as the sequence of flows and their mutual relationships, and the presence of devitrification, of spherulitic structures, and in particular of evidence which has been interpreted as indicative of the operation in some rocks, after consolidation, of processes connected with the magmas from which these rocks were derived; (b) a petrographical description of the rocks, taken in groups.

Royal Society of New South Wales, July 1.—H. Leighton Kesteven: (1) A third contribution on the homologies of the parasphenoid, ectopterygoid, and pterygoid bones, and of the metapterygoid. (2) The parabasal canal and the nerve foramina and canals in the bird skull. The application of Gaupp's designation "parabasal" to the carotid canal and the demonstration of the course of the palatine branch of the facial nerve serve to emphasise resemblances to the reptilian conditions.—A. R. Penfold: Note on the identity of uncineol with eudesmol. Uncineol ($C_{10}H_{18}O$, $[a]_D^{20} +36.99^\circ$; melting-point, $72.5^\circ C.$) is an alcohol which appears to bear a close resemblance to one of the terpineols, isolated in 1907 by Messrs Baker and Smith from the essential oil of *Melaleuca uncinata*. The more recent investigation has shown this substance to be identical with the sesquiterpene alcohol eudesmol. The chemical and physical characters are: Melting-point, $80.5-81^\circ C.$; boiling-point, $155-156^\circ C.$ at 10 mm.; specific rotation, $+33.45^\circ$; molecular weight deter-

minations, 221 and 227; molecular formula (combustion results), $C_{15}H_{26}O$; melting-point of dihydrochloride, $75-76^\circ C.$ —Sir George Knibbs: Multiple births, their characteristics and laws mathematically considered. Considering the question of masculinity of population generally, of live-births, and of the still-born, it is shown that the preponderance of males is most marked in the last, being about 21.9 per cent. greater than that of live-births. In Australia, as the masculinity of the general population decreases, that of the live-births increases. Applying the theory of probability to the occurrence of twins, about 76 per cent of the cases are from two ova, and about 24 per cent. from one ovum. In the latter case the pair may be either both male or both female, and have a common chorion, while twins born from two ova are indifferently male and female, two males, or two females, and each has its separate chorion. Only about 10.9 per cent. of triplets are from three ova, while in 69.1 per cent. there is a division of one of the ova into two. There is an increase of the liability of twins with the age of the mother each year from 12 years to 39 years, when it diminishes, nearly by the same amount each year of age, until it becomes nothing at age 54. This greater liability with age to twins increases with the duration of marriage and with the number of previous confinements.

The Coal Resources of Great Britain.

TO all sections of the community, the state of the coal mining industry in Great Britain is a source of great anxiety. The real difficulties which the industry has to face depend upon causes which are very deeply rooted. We were the first nation to develop our coal resources extensively and, owing to the fact that we had originally magnificent coal seams lying at no great depths, and above all, that our coal-fields lay close to the seaboard and within easy access of excellent harbours, we built up the magnificent coal trade upon which we justly pride ourselves. Coal, our main national asset, is unfortunately a wasting asset; once extracted it can never be replaced. At the present moment we are practically producing 23 per cent. of the world's coal output, whilst we have only $2\frac{1}{2}$ per cent. of the world's coal resources; in other words, we are drawing upon our coal reserves nine times as fast as the rest of the world, and these reserves are therefore gradually approaching extinction.

At the present moment, however, what we have to fear is not the exhaustion of our coal supplies so much as the increased cost of our coal production, which makes it impossible for us to compete with other nations for the coal trade of the world. This increase in price is no doubt to some extent due to natural causes, but to a far greater extent has been brought about artificially. Unless we can produce coal as cheaply as the nations with whom we are brought into competition, our coal trade, and with it the whole nation, must decline. The cost of coal production is made up of many items, into all of which wages enter to a greater or lesser extent, but direct wages make up about two-thirds of that cost. It depends, therefore, entirely upon labour whether our coal trade is to prosper or to suffer gradual annihilation. It must be emphasised in the strongest possible terms that this insistent demand for cheap production does not by any means necessarily imply low wages per man employed; it does require a low wages cost per ton of coal produced; in other words, the key to the situation lies in the maximum production per worker engaged in the industry.

In the United States of America, the cost of coal production is roughly two-thirds of what it is in Great Britain (12s. 8.4d. per ton as against 19s. 0.69d.); nevertheless, the men engaged earn much better wages, simply because the output per man is so much higher (3.82 tons per shift as against 0.928 ton). This fact is due in part beyond doubt to natural causes, but is also due to the fact that the men themselves work hard and that the Trade Unions have always opposed anything like a "ca' canny" policy. These same reasons furthermore help American collieries to develop extensively mechanical methods of machine mining. It is often overlooked that a severe limitation of the hours of labour, such as we have in Britain, prevents the extensive adoption of coal-cutting machines; these can only be used to advantage if they are kept actively employed. A colliery cannot afford to put capital into such machines if they are only to be worked six hours out of the twenty-four, and this consideration doubly handicaps our coal industry.

When the future of the industry comes to be considered, it may well be found that neither American nor German competition will prove so formidable as competition from China, India, and South Africa. The price of coal at the pit's mouth in these countries is only about one-third of our own, and their immense coal resources necessarily bring them into prominence in discussing the future of the British coal industry. It is true that we have the advantage of a well-established coal trade, which has developed as a natural consequence of so many of the British coalfields being so well situated geographically, and it is true that trade is loth to leave the channels in which it has been accustomed to flow. Certain of our labour leaders, however, by their continuously repeated threats of strikes, are demolishing that confidence in Britain's ability to supply the goods as and when customers require them, which formed the real basis of Britain's supremacy in the coal trade, and without which the maintenance of that trade is impossible. Once that South Africa has developed and organised suitable transport facilities and has built up for itself the trade which our internal dissensions have turned from us, our chance of competing is gone. Even now it is going; for some years past Natal has been competing successfully in the Bombay markets with British and Indian coals.

It seems impossible to avoid the conclusion that we cannot hope to regain the position which we once held, that of the world's chief manufacturers, as this was based essentially upon the fact that we were able to produce coal in any desired quantity more cheaply than could any of our competitors, and the question which to-day is the most insistent is whether anything can be done, if not to restore our lost supremacy, at any rate to find some new method of utilising our coal to advantage, so as to save us from national extinction.

The situation is reviewed in an interesting article by Mr. Lancelot Lawton on "Coal and the Future" in the August issue of the *Fortnightly Review*. With most of the views therein expressed the majority of serious students of the economics of the coal industry will cordially agree, although there are several points to which exception may be taken. Thus the author commences with the statement that "the critical condition of the British coal-mining industry is due to the fact that to a large extent thicker seams at moderate depths are being exhausted"; the fact of this exhaustion is sufficiently well known, but working at moderate and even considerable depths is to-day no longer a serious problem. With modern methods of engineering, the increase in the working cost of winning coal from deep-lying seams is negligible, as witness the fact that the only collieries in Britain that are working to-day under anything like satisfactory conditions are the deep pits in the concealed Yorkshire coalfield. The real crux in the working of deep seams lies in the vastly greater initial outlay required, but, once capital can be assured that it will get an adequate return for its employment in such a relatively risky undertaking, depths of even of a thousand yards can no longer be considered a real obstacle to economic working. It may fairly be said that in spite of the wild talk of Socialists, one of the serious problems that

confronts the coal industry is how to inspire capitalists with this assurance; collieries inevitably become exhausted in the process of time, and if our coal trade is to be maintained, new pits must be sunk and new collieries opened out. Needless to say, this can only be done if the capitalist is assured that the investment involves only a fair business risk.

Like many others, Mr. Lawton pins his faith in the regeneration of the coal industry upon the general employment of low temperature carbonisation, with its attendant production of oil and other bye-products. Low temperature carbonisation is, however, by no means yet as assured of success as many seem to think, for they generally overlook not only the mechanical difficulties, but also the chemical difficulties which the process presents, such as are well indicated in the paper on the "Study of the Tars and Oils obtained from Coal," by Messrs. Sinnatt and King, read at Leeds at the recent meeting of the Chemical Engineering Group of the Society of Chemical Industry. Furthermore, there are other processes to be taken into account; it may fairly be said that for the production of oil from coal the Bergius process would seem to promise to rival, if not to surpass, low temperature carbonisation; the "Synthol process," based upon the interaction between carbonic oxide and hydrogen, also must not be left out of account, although this is not an industrial process to-day. Fischer, in his recent work on the conversion of coal into oil, translated by Lessing, says: "The Synthol Process, combined with primary tar production, likewise indicates the possibility of a total conversion, and indeed offers, in my opinion, the best promise for the future."

In view of these and many other possibilities which the scientific research of coal, now actively pursued in many quarters, is opening up, it is more than doubtful whether it would be a wise policy to-day to embark upon the construction of costly low-temperature carbonisation plants. A few years may well see this process relegated to the background and displaced by some more profitable method.

Capitalists are surely wise in waiting to see which process is likely to be the most advantageous before spending money on plants, which, for all we know to-day, in a few years may have only a scrap-iron value.

It is greatly to be feared that any remedy based upon the treatment of coal after it is won would not help the situation. As Mr. Lawton truly enough points out, any improvements in the utilisation of coal cannot possibly be confined to Britain, but will be universally adopted by other nations engaged in coal production, so that we necessarily come back to the economic proposition that the future of coal rests with those nations that can produce it cheaply. There is, in fact, only one remedy for the present critical position of the British coal industry, and that is the cheaper production of coal, which, as already said, means a greater output per man employed in the industry. A colliery that is unable to produce coal at a price less than the coal is worth in the world's markets is not a national asset but a national liability so long as it continues to work, and no method of treating the coal after it has been raised can possibly alter that cardinal fact.

HENRY LOUIS.

Science on Exhibition.

Phases of Modern Science. Published in connexion with the Science Exhibit arranged by a Committee of the Royal Society in the Pavilion of His Majesty's Government at the British Empire Exhibition, 1925. Pp. vii + 232. (London: A. and F. Denny, Ltd., 1925.) 3s. 6d.

THAT a space should have been set aside for scientific exhibits at the British Empire Exhibition is a compliment, well deserved but not the less welcome, to the progress of modern science. That the task of filling this space should fall upon the Royal Society was inevitable, and it would certainly be difficult to conceive, and impossible to convene, a stronger committee than that appointed by the Society for the purpose. The volume which we have before us, with the title "*Phases of Modern Science*," contains a record of its second and revised version of a scientific exhibition. The actual guide to the exhibits occupies the second and smaller portion of the book. The first and larger part consists of articles, by many of our most eminent men of science, dealing, more or less directly, with the subjects which the exhibits are intended to illustrate. Chemistry is not dealt with, the exhibits in this branch of science having been arranged by the Association of British Chemical Manufacturers in the Palace of Industry.

There is a notion current that scientific workers are shockingly bad showmen. They are accused of being in possession of all kinds of fascinating secrets which they are either unwilling or more probably incompetent to communicate. They are supposed, through some defect in their education, to be unable to speak in language understood by the people, and from time to time journalists have attempted to translate this scientific jargon into their own, with results which have not always been happy. We think that a careful study of the articles in this volume should convince any unprejudiced reader that the accusation is without any real basis. It is difficult to imagine how the present state of our knowledge of radiation, for example, could be expressed more simply and, we may add, more delightfully than in Sir Oliver Lodge's introductory article on "*Radiation*," or how recent advances in astronomy, made as they were by a masterly combination of physical imagination and mathematical analysis, could be conveyed more happily than in Prof. Eddington's article on "*The Interior of a Star*." If it is not invidious to pick out one article when so many are good, this contribution of Prof. Eddington, which is abstracted from a Royal Institution discourse, strikes us as a model of popular scientific exposition. Sir Ernest Rutherford on "*Electricity and Matter*,"

and Dr. Aston on "*Atoms and Isotopes*," are almost equally successful.

It is not, of course, to be assumed that these articles can be followed entirely without effort by a reader devoid of scientific knowledge. The temple of science is, unfortunately, not furnished with lifts, and whosoever would ascend to the upper stories, where building is in progress, must be prepared to do a little climbing, however skilful his guide may be. The phases of modern science dealt with in this volume are the culmination of many years of scientific discovery and research, and some knowledge of this preliminary work is necessary, not merely for understanding but even for enjoyment. The delight of the spectators when a conjurer produces a rabbit from a top-hat is founded on their previous knowledge of the natural history of top-hats and rabbits, and the thrill which the scientific world experienced when Sir Ernest Rutherford produced hydrogen from nitrogen is similarly based on some previous knowledge of the chemistry of these substances, and is not to be achieved by one to whom both hydrogen and nitrogen are equally unknown. It is to such inherent difficulties, and not to any lack of showmanship, that we must ascribe the hiatus which we all deplore between the scientific worker and the public.

All parts of science do not present equal difficulties, and, it must be confessed, all eminent men of science do not possess the same facility for popular exposition. In the "*Circulation of the Atmosphere*," and in the "*Water in the Atmosphere*," Sir Napier Shaw and Dr. G. C. Simpson have subjects which appeal to the man in the street, ever interested in that perennial source of conversation, the weather, and deal with them in a way which will appeal not only to the general reader but also to the scientific worker who has not hitherto chanced to stray down the interesting by-path of meteorology. Prof. Fowler, on the other hand, in the "*Origin of Spectra*," and Dr. Chree in "*Atmospheric Electricity*," are clearly writing for students of science, and make no attempt to reach the uninitiated. Both articles are good of their kind, and Dr. Chree's, in particular, is a valuable summary of facts and phenomena which the physicist does not usually stumble across in his ordinary reading.

Of the biological articles, which occupy a somewhat unduly small space in the volume, the majority deal more or less directly with the theory of evolution and natural selection. The conclusions drawn are not such as would commend themselves to the stalwart "*Fundamentalists*" of Tennessee. In this portion of the book the present reviewer can claim to be in the position of the general reader, and can testify from personal experience that, though he can understand the complaints

which are lodged sometimes at too free a use of technical language by scientific writers, these biologists have certainly succeeded in "getting their ideas across." His only regret is that they do not fill a larger space in the bill. There are, however, strict limits to the amount of printed matter which can be sold at the modest price of this volume.

Of the exhibits themselves it may be said, in conclusion, that they prove that to his own peculiar audience, the man of science can be an incomparably fine showman. The fact that the exhibits are confined almost wholly to the more recent developments of science makes it inevitable that their principal appeal should be to the serious student of science. To the younger students, and particularly to those from the smaller seats of learning, somewhat remote from the larger institutions where the tide of research flows at its fullest, this collection has been a source of inspiration and delight. By them, at any rate, this little volume will be cherished as a memento of a memorable event, while many others may find in its introductory articles a pleasant and convenient means of learning, on the best authority, the present position of knowledge and conjecture in phases of modern science which are not peculiarly their own.

The Realm of Plants.

Plants and Man: a Series of Essays relating to the Botany of Ordinary Life. By Prof. F. O. Bower. Pp. xii+365. (London: Macmillan and Co., Ltd., 1925.) 14s. net.

IF an extra-terrestrial observer, gifted with super-human powers of ocular accommodation and unhampered by human prejudices as to man's position in the scheme of things, were given the opportunity of surveying with detachment the myriad-patterned pellicle of life that invests the earth, the function of the human species might afford him material for confusing speculation. As he gazed on some parts of the planet he might be driven to entertain an Erewhonian conception of man's relation to machinery, but, surveying the greater part of the land surface, he might well be excused for concluding that man's chief function was the distribution of certain dominant species of plants, for he would see almost everywhere men toiling to spread the triumphant grasses and a host of other less dominant but still powerful green organisms. In this view of man's relation to plants, our extra-planetary philosopher would not be without a certain amount of human concurrence, for to a large section of humanity a seductive species of *Rosaceæ* represents the primal cause of man's introduction to that distasteful (?) form of activity known as work.

Although in his latest book Prof. Bower has not expounded the polity of plants from quite such a Saturnian point of view, both the order of its title, "Plants and Man," and the presentation of its matter, are not without a tincture of such significance. His theme is the mutual reactions of plants and man, skilfully leading on to the final vision of the fundamental dependence of man on his fellow-creatures the plants for all that he has become and yet may be. It is impossible within the compass of a review to give an adequate idea of the multifarious relations between plants and man so succinctly and clearly presented in the thirty essays that form the book, and an attempt at a general indication of its contents must suffice. The first five essays are devoted to the green cell that tints the continents and islands, and is the foundation of all life thereon and in the sea, and to the general scheme of construction and the vital processes of the complicated commonwealth of cells that forms plants. The influence of the seasons is touched upon in another essay, and after this general introduction the reader is taken in pleasant and suggestive discourse by meadow and pasture, through woodland, over moor and mountain, and along the shore.

From these varied and extensive excursions we come to the only relation that plants have to "play." The struggle for existence and supremacy amongst themselves, although it might permit rest, would allow of no indulgence in "play," even if it were not inhibited by the line of life they have chosen, but in the share they take in the formation of golf links and playing fields, plants make some amends to man for his expulsion from an idle Eden. After play comes consideration of man's most intimate active relation with plants, that fundamental form of work, cultivation, which under flowers and fruits, vegetables and grains, is discussed with a wealth of allusion and illustration. Human interest in a derivative form of work, engineering, gives the keynote to three essays on the mechanical construction of plants, and on the methods by which they have solved the mechanical problems forced upon them by the conditions of their life, and have anticipated many of man's engineering devices. The physical properties of wood and bast, which permit of an amazing range of application from house-building and cloth-weaving to the divine music of the violin, are the subject of two chapters. In their final function in completing the full circle of the wheel of life, which starting from the inorganic, through the green cell returns to the inorganic through fungi and bacteria, plants are shown as the earth's prime sanitary agents and indispensable to man in his most advanced sanitary practice.

The close social life of plants and the various

expedients—ranging from mutually beneficial co-operation to the worst forms of parasitism—by which plants attempt to cope with the ever-pressing problems of over-population and unrestricted competition are admirably outlined in several chapters. These same problems bid fair to be the supreme ones of the future for humanity also, and in the human handling of them the world of plants is not only a living lesson and a warning, but will dictate some of the most important conditions for their solution. It is, therefore, well that the note of the concluding essays should be man's dependence and influence on vegetation. Prof. Bower rightly emphasises the tragic aspects of man's interference with the balance of plant life—and, as a consequence thereof, with animal life also. In this, as in other things, the evil wrought by one generation lives after it to plague those that follow. Happily one need not yet conjure up the dreadful vision of a day when man will have brought it about that over all the earth the desert will be the only contrast to the sown, but much depends on man using his powers with more discrimination in the future than he has in the past. It is in helping to spread appreciation of this, no less than in its enjoyable presentation of the life and work of plants themselves, that Prof. Bower's book has a value all its own.

Ether and Erdgeist.

Ether and Reality: a Series of Discourses on the many Functions of the Ether of Space. By Sir Oliver Lodge. (The Broadcast Library.) Pp. 179. (London: Hodder and Stoughton, Ltd., 1925.) 3s. 6d. net.

EVERYTHING that Sir Oliver Lodge writes bears so clear an imprint of his powerful and persuasive personality that a book bearing his name may be confidently anticipated to hold the reader's interest and stir his imagination. In the present little work such an expectation is not disappointed. Sir Oliver has a well-known enthusiasm for a massive, elastic, all-functioning ether of transcendent reality, and his whole-hearted belief finds expression in a lively, yet learned, eloquence which does justice to his theme. He treats of the ether in the most comprehensive spirit, and his book contains not only a survey of all the wider problems of physics in connexion with which an ether may be invoked, but also philosophy, elevating moral reflections, and an inspiring vision of the perfectibility of man.

The point of view is, perhaps, best expressed by a sentence taken from the chapter on "The Ultimate Physical Reality": "Speculatively and intuitively we feel to be more in direct touch with the ether than with matter." Sir Oliver regards the ether less as a working

hypothesis than as a revealed reality. He sees in it a possible vehicle for psychical manifestations of man's individuality—consciousness, memory, and affection. "It is the primary instrument of Mind, the vehicle of Soul, the habitation of Spirit. Truly it may be called the living garment of God." It is in almost these words that the Erdgeist in Goethe's *Faust* speaks of his activities:

"So schaff ich am sarsenden Webstuhl der Zeit
Und wirke der Gottheit lebendiges Kleid"

It is not on physical evidence alone that Sir Oliver relies, but on something of the mystic inspiration and psychic experiences which prompted the great poet's words.

In spite of the charm and simplicity with which the book is written, some difficulty may be experienced in understanding exactly what Sir Oliver wishes to lay down as regards the physical properties of the ether. For example, he says that the fact that the ether transmits waves proves that it must possess elasticity and inertia, because material bodies that transmit waves have these properties, and then says: "The possession of these properties makes the ether very real" But as the possession of a quasi-material mechanism must be postulated in order to endow the ether with these properties, this does not, to the present writer, appear convincing. Again, he says at one place that "Ether is not to be explained in terms of matter," but this, apparently, does not mean that the ether is not to be given many properties of matter. At the heading of one chapter he quotes a passage from Einstein containing the words: "But this ether may not be thought of as endowed with the quality characteristic of ponderable media," yet he nowhere discusses the difficulty presented by the fact that the ether cannot be used as a frame of reference. The present writer has no desire to carp: he gratefully acknowledges the pleasure he has got from reading the book, yet he cannot see what is gained by calculating a mass and an elasticity for an ether which has not the properties of a ponderable medium, so long as these properties of mass and elasticity serve only to explain the very transmission of waves which is the ground for their postulation. Of course, if they helped to understand cohesion or gravitation, of which Sir Oliver explains the ether to be the seat, or the behaviour of light in the neighbourhood of gravitating matter, every one would welcome them, but, as it is, to some they may well seem *entia praeeter necessitatem multiplicata*. There is, by the way, nothing said of the possibilities of Silberstein's ether of variable density, condensed at the surface of material bodies, which recent experiments suggest will have to be seriously considered.

The book is, of course, intended for non-technical

readers, and is bound to have a wide circulation and give delight to very many. The points that have troubled the present reviewer are very possibly not such as will trouble those approaching the book with a wider outlook. The general spirit of the little book is admirable, and, after all, that is what counts.

- (4) *Inorganic Physical Chemistry.* By Prof. G. H. Cartledge. Pp. xvi + 463. (Boston and London: Ginn and Co., Ltd., 1924.) 22s. 6d.

(1) PROF. FINDLAY'S "Physical Chemistry for Students of Medicine" recalls in its appearance as well as in its literary qualities the books by this author which are already familiar to all students of chemistry. It is, however, only necessary to read as far as the title of the second chapter, "The Aqueous Milieu of the Life Processes," in order to realise that the biological aspects of physical chemistry have been thrust into the forefront, in order to secure the interest and attention of the medical student, since it is not usual for a physical chemist to describe his favourite aqueous solutions and suspensions under so foreign a designation. The writer of such a book as this can achieve his object most readily by teaching the familiar and fundamental truths of his science with the help of novel illustrations derived from that field of applied science in which his readers are interested. We therefore find the problems of solubility, surface tension, viscosity and osmotic pressure illustrated by reference to the behaviour of blood and urine, and to the plasmolysis of cells or the hæmolysis of blood-corpuscles. This method, when used by a teacher of experience, not only interests the reader, but also has the further advantage of showing him how to apply the methods of pure science to his own specialised studies. No proof is needed to establish Prof. Findlay's skill as a writer on physical chemistry: the present volume appears to the reviewer to prove that he has at least familiarised himself sufficiently with the biochemical aspects of his

subject to enable him to provide a useful guide for biological workers who wish to join him in this field of work.

The author will perhaps pardon, as a personal weakness of the reviewer, the prejudice which makes him regard it as a retrograde step, after teaching the student to write the formula of an amino-acid as an internal salt, $\text{NH}_3^+ \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{O}^-$, to finish by asking him to regard this ion as having neutralised its two charges by swallowing its own tail, after the manner of a fried whiting. It is not every fish that can be induced to perform this acrobatic feat, and Pfeiffer's proof that "distance is no object" in preparing a betaine from an amino-acid, since these can be produced from *meta* and *para* as readily as from *ortho* aminobenzoic acid, seems to provide conclusive evidence that the amino-acids are under no obligation to strain their backbones in the manner suggested.

(2) Prof. Urbain's book on "The Energetics of Chemical Reactions" is the third volume of a new "Collection de Physique et Chimie," of which two preceding volumes, on "Colour and Chemical Constitution" and on "Thermochemistry," have already been reviewed in these columns (May 24, 1924, p. 739, and August 16, 1924, p. 240). Prof. Urbain claims that physical chemistry is not merely the overlapping section of physics and chemistry, but that it is a pioneer science which opens up new fields, which are afterwards added to the domain of these two sciences. He gives to his illustrious colleague, Le Chatelier, the credit for having been the first in France to introduce thermodynamics into chemistry, and asserts that "at the present time no one can call himself a chemist if he ignores the principles of thermodynamics and the method of applying them correctly to chemical phenomena in general, and more particularly to chemical equilibria." Such a test, if applied rigidly, would certainly exclude from the author's chemical "kingdom of heaven" some of our very "rich men," whose wealth of knowledge and experience could not be squeezed through the "needle's eye" of chemical thermodynamics. Whilst, however, we may repudiate the idea of excommunicating all those of our colleagues who are repelled instead of being attracted by the mathematical treatment of chemical problems, there is much to be said for the author's policy of writing a book on thermodynamics from the point of view of the chemist, rather than of the physicist or mathematician, and so minimising the difficulties of assimilating this method of treatment.

The book is in three parts, an introduction, which covers the general principles of thermodynamics, a very short section on thermochemistry (which has already formed the subject of a separate volume of this series),

and a third section, filling more than half the volume, on the "Modern Theory of Affinity." The treatment ignores all "atomic" explanations, not because they are regarded as of no value, but simply because they are superfluous to the object immediately in view. A further volume of the same collection is promised, in which the applications of the principles now taught will be discussed for their own sake, instead of being used merely as illustrations of general principles.

(3) Prof Urbain's book on elements and atoms is issued under the general heading of "Science and Civilisation" instead of "Physics and Chemistry." It deals with the definition of an element, radioactive elements, the constituents and structure of the atom, the relation between the properties of elements and the constitution of their atoms, and finally with isotopes. The International Table of Radioactive Elements is given on a folded sheet at the end of the volume. The author's style is attractive and interesting, and although he is addressing himself to an audience of general readers, his views on the question of how an element should be defined have a special interest at the present time for chemists. This question is discussed in a chapter of 50 pages, which occupies nearly one-third of the book, and the final conclusion, that the International Commission of the Chemical Elements was right, when in 1923 it reported that "an atomic number is necessary and sufficient to define a chemical element," is qualified by a final paragraph which contains a single brief sentence, asking whether "in the physical sciences, all definitions must not be only provisional?"

(4) Prof Cartledge's book appears to have been written in order to meet the need, in the curriculum of the Johns Hopkins University, of providing instruction in physical chemistry for undergraduate students, at such an early stage in their course that they cannot be assumed to be familiar with organic chemistry. This has led to the production of a book in which particular emphasis is placed upon the properties of aqueous solutions, including especially such subjects as hydrolysis, acidity and the formation of complex ions. Fortunately the author has not gone to the extreme limit of excluding *all* organic compounds from his consideration, since he has found it necessary to illustrate the vapour-pressures of aqueous solutions from the case of mannitol, their osmotic pressure by data for sugar-solutions, whilst the cryoscopic and ebullioscopic methods of determining molecular weights are illustrated by the use of benzene and other organic compounds as solvents. A still more notable example is that of "The Speed of Reactions," where the principal actions studied are derived from the field of organic chemistry.

Apart from sheer necessity, this subdivision of the field of physical chemistry appears to the reviewer to be wholly undesirable. Physical chemistry has now emerged from the grotesque stage in which it appeared to concern itself exclusively with the study of *dilute aqueous solutions*, and when Faraday was not classed as a physical chemist because his work was published before the foundation of the *Zeitschrift für physikalische Chemie*; the limitations imposed in the volume now under review have the effect of replacing the old fetters, and of making the least typical of liquids appear as the only typical solvent. Such limitations are entirely retrograde, and it is to be hoped that other universities will escape from the necessity of imposing them upon their teachers of physical chemistry.

T. M. LOWRY.

Climates of the Past.

Die Klimate der geologischen Vorzeit. Von Wladimir Koppen und Alfred Wegener. Pp. iv + 256. (Berlin: Gebrüder Borntraeger, 1924) 11s. 6d

THIS monograph on the climates of the past is essentially a supplement to Prof Wegener's work on continental drift. It endeavours to show that the former variations of climate can be best explained by Wegener's theory that all the land on the earth was originally one continuous continent which has been broken up, that the pieces have drifted apart, and that the north and south poles have migrated to their present positions.

The authors first discuss the nature of the geological evidence of former climates, and they claim, amongst other points, that all the great coal formations have originated either on moraines or on beds that have been recently folded. They then describe the distribution of climate in the Carboniferous and Permian Periods, and one of the most useful contributions in the book is the account of the glaciation of parts of the ancient continent of Gondwanaland, the section on the South American evidence is especially valuable. They next discuss the climatic zones in the Mesozoic and the Kainozoic, and follow with a chapter on the records of pre-Carboniferous glaciation which accepts without hesitation some cases that are regarded by some authorities as highly doubtful, and omits reference to other records. The final chapter discusses the Quaternary glaciation, which it attributes to variations in solar radiation.

The book gives tables of the solar changes in radiation for the past 800,000 years, and endeavours to fix the date of the successive glaciations. The discussion of the causes of the Pleistocene glaciation by two distinguished meteorologists shows that the theory of

its dependence on changes in solar radiation must be seriously considered.

The geological section of the book is a compilation of the facts which appear to support the authors' thesis, but it is often unconvincing from unfortunate selection of geological evidence. They accept, for example, the existence in the Silurian rocks of Bohemia and the Hartz Mountains, of *Lepidodendron*, *Stigmaria*, and *Sphenopteridium*—a conclusion which, if accepted, would render futile all recent palæo-botanical discussions on the beginning of the land flora. The authors' claim that the variations of former climates can be explained by a shift in the positions of the pole combined with a drift of the continents is not convincing even on their own evidence. Their work is most detailed in reference to the climate in the Carboniferous Period; yet the *Squantum* tillite occurs exactly on their Carboniferous equator; they reject that formation as pseudo-glacial, but it requires stronger evidence than the authors bring forward to explain it by any non-glacial theory. The distribution of the Jurassic climate also appears more consistent with Neumayr's view of zones concentric around the present poles than with the position the authors assign to the Jurassic poles, as they carry the boreal province within 20° of their equator.

The book has no index, which is an especially unfortunate defect, as its chief value rests on its extensive collection of information as to former glaciations and biological distribution from the scattered literature on those subjects. The book will be more useful from its summary of little-known facts than convincing of the authors' theory.

Our Bookshelf.

Contributions to Embryology. Vol. 16, Nos. 78-84. (Publication No. 361.) Pp. 276 + 32 plates. (Washington: Carnegie Institution, 1925.) n.p.

THANKS to the munificence of the late Mr Andrew Carnegie, American embryologists are enabled to place the results of their inquiries before the world in a superb form. The sixteenth volume of "*Contributions to Embryology*" maintains the high standard set by its predecessors, text and illustrations are excellent and the "contributions" are deserving of them.

The present volume, which includes seven papers, illustrates the new departures which are being made from recognised orthodox methods by modern embryologists. Only three of the seven papers follow conventional lines. Dr. F. Payne gives clear and exact drawings of reconstructions made of a human embryo in the fourth week of development; Dr. Cecil M. West makes a welcome contribution to later stages in the development of the gums and tooth-buds of human fetuses, while Dr. G. B. Wislocki describes certain new features in the placentation of the sloth (*Bradypus*

griseus). Prof. Alex. Maximow approaches the problems of embryology from the experimental side. He describes the behaviour of parts taken from embryos of rabbits and kept alive for various periods by methods adopted for the culture of living tissues. The results throw light on that kind of tumour which occurs occasionally in human beings and is known as an embryoma.

In a series of three papers, Prof. Florence Sabin, in collaboration with Dr. C. A. Doan and R. S. Cunningham, attacks the old problem of the origin of blood corpuscles by a new route—a physiological route. They have studied the production of new blood corpuscles in animals which had been rendered anæmic, using vital stains for the detection of the various kinds of corpuscles which are then produced. The result is the construction of a new schema of the ancestry of all kinds of cells which appear in blood or free cells which may be encountered in the tissues outside blood-vessels. Of great clinical importance is their discrimination of two forms of phagocytes—the clasmatoocyte, which arises from the endothelial cells lining capillaries, and the large monocyte which is produced from cells occurring in reticular connective tissues of all sorts; the latter, unlike the clasmatoocyte, arises outside a capillary lumen. It will thus be seen that modern embryology becomes more and more a branch of experimental research.

General and Physiological Features of the Vegetation of the more Arid Portions of Southern Africa, with Notes on the Climatic Environment (Publication No. 354) By. W. A. Cannon. Pp. viii + 159 + 31 plates. (Washington: Carnegie Institution, 1924) n.p.

THE author of this volume spent six months' leave in South Africa in the latter half of 1921. During that time he introduced Livingston atmometers to South African botanists, distributed through the Director of the Union Botanical Survey a number of standardised atmometers at various stations through the Union, and arranged for the recording of weekly evaporation; he visited the principal arid and semi-arid regions, sampled the characteristic plants and the transpiring power of their leaves, examined the leaf anatomy and root systems of Karroo plants, and took a number of excellent photographs. In the volume under notice the photographs are beautifully reproduced and the data he collected are brought together.

South African botanists will find much to interest and stimulate them, and will welcome the impressions of an observer with so varied an experience of arid regions, who can compare from first-hand knowledge the vegetation of the drier parts of their country with that of other parts of the world under comparable climatic conditions. His example will strengthen the movement already evident, from purely floristic towards ecological investigation of the South African flora. He has directed attention to those features of the plants which are of special importance in connexion with their water relations; and he has demonstrated that with a few simple appliances physiological data of value can be obtained out on the veld. Observations were even made on the transpiration of *Il'ehoutschia mirabilis* in the Namib desert; they suggest that the leaves of this curious plant transpire far more freely

than might have been anticipated from their xerophytic structure and the extreme aridity of the environment.

The atmometric data are somewhat disappointing. It is clear that they require a scrutiny to which the author had not been able to subject them at the time of publication, and are not uniformly trustworthy. A "Fig. 8" representing some of the data graphically, is referred to on pp. 44 and 55, but is not to be found in the book. There are also a regrettable number of printers' errors which have escaped correction. For example, "casual" appears in two successive lines on p. 3, in one or other of which it should surely read "causal"; while two variants on "Matjesfontein" appear on pp. 68 and 71. The "typography" of a district is referred to on p. 69, "Protaceae" for "Proteaceae" on p. 110, and so on.

Mechanical Refrigeration: being a Practical Introduction to the Study of Cold Storage, Ice-making, and other Purposes to which Refrigeration is being Applied. By Hal Williams. New and enlarged edition. (The Specialists' Series.) Pp. x+501+6 plates. (London: Sir Isaac Pitman and Sons, Ltd., 1924.) 20s. net.

THE volume under review is a new edition of Mr. Hal Williams's well-known book on mechanical refrigeration, which has now been amplified and largely rewritten. It contains a useful summary of the present state of our knowledge of refrigeration in its broadest aspect, and, as it does not go unduly into minute detail of design and equipment, it will appeal to all interested in the vital problem of the conservation of the food supply of the nation.

The book is descriptive rather than theoretical in its treatment of the subject, and a valuable feature is the account given of recent applications of refrigeration to such industries as paraffin crystallisation, mine shaft freezing, and so on. Another noteworthy feature in the new edition is the attention given to the high-speed total enclosed compressor. This type of compressor is an important step in the development of refrigerating machinery which has been taking place in recent years.

The general lay-out of the book partakes more of the nature of a dictionary than a text-book, for each paragraph is sub-headed under such titles as "Unit of Pressure," "Liquid Coolers," "Buying Machinery." This facilitates the use of the volume as a work of reference. The illustrations are plentiful and include a number of folding plates, but it is questionable whether these justify their cost in a book of this character. The author has given a prominent place to one very important application of refrigeration, namely, the overseas transport of fruit, for this industry is destined to be a vital factor in the development of the British colonies.

E. G.

A Catalogue of the recent Sea-Urchins (Echinoidea) in the Collection of the British Museum (Natural History). By Hubert Lyman Clark. Pp. xvi+iii+250+12 plates. (London: British Museum (Natural History), 1925.) n p.

DR. H. LYMAN CLARK, of the Museum of Comparative Zoology, Cambridge, Mass., who is one of the outstanding authorities on echinoderms, has given in this catalogue the results of his studies, extending over

some months in 1924, of the British Museum collection. This has been known as one of the important collections of sea-urchins since the time of J. E. Gray's first connexion with the Museum in 1824, in which year he published a paper—dealing with about 50 species—which may be regarded as the foundation for a catalogue. For thirty years Gray continued his study and, at intervals, his publications on sea-urchins. Since his time the collection has received notable additions from the expeditions of the *Challenger*, *Alert*, *Penguin*, and *Egeria*, from the collections made by Prof. A. Willey and Prof. J. Stanley Gardiner, and from those made during the recent British Antarctic Expeditions; it now ranks as one of the foremost collections of the world. It contains about 8000 specimens representing 382 species grouped in 146 genera, and Dr. Clark directs attention to the wealth of large examples in many of the series. He gives a table showing that in the collection is type material of 111 forms, 25 of which are new species or varieties described in this volume.

Dr. Clark has made available to students of the Echinoidea an accurate account of this great collection, and his catalogue serves also as a handbook for the identification of most sea-urchins. Twelve excellent collotype plates provide illustrations of the new species.

Recent Advances in Medicine: Clinical, Laboratory, Therapeutic. By Dr. G. E. Beaumont and E. C. Dodds. Pp. xii+292. (London: J. and A. Churchill, 1924.) 10s. 6d. net.

THE rapidity with which the study of medicine advances makes it necessary for the physician and clinical pathologist to keep constantly in touch with new methods of investigating and treating disease. With limited time and material for research, it is impossible for the busy practitioner to test these for himself, or to isolate from the vast accumulation of recent medical literature what is likely to be of practical value. In "Recent Advances in Medicine" a physician and a biochemist collaborate to give an account of the more important changes in clinical and laboratory routine methods of the last decade, and to indicate the relative value of the results obtained. The book covers a very wide field, including such subjects as blood analysis, renal, hepatic, and pancreatic functions, test meals, the polygraph and electrocardiograph, artificial pneumothorax, and various cutaneous and serological tests. Some of these might with advantage have received less attention; for example, the electrocardiograph and its tracings are of little value except to the specialist. X-ray investigation of the stomach, to which less than a page is devoted, is of far more interest to practitioner and student.

The book will be welcomed as a very useful addition to the practitioner's library. It contains numerous references and is excellently indexed.

Conformal Representation. By Leo Lewent. Translated by Dr. R. Jones and D. H. Williams. Pp. viii+146. (London: Methuen and Co., Ltd., 1925.) 7s. 6d. net.

THE work under notice is a translation of Dr. Leo Lewent's "Conforme Abbildung" (Teubner). It opens with an account of functions of a complex variable from the Cauchy-Riemann point of view. A long

chapter is devoted to special transformations, with detailed discussion of linear transformations and stereographic projections, but without reference to group theory. The account of algebraic transformations necessarily introduces Riemann surfaces, the two-sheeted ones being mainly considered. Riemann's conjecture, that any simply connected surface can be represented uniquely, continuously, and conformally on the area of a circle, has been made the foundation of many brilliant investigations by such mathematicians as Heine, Schwarz, Weierstrass, Osgood, Poincaré, and Koebe. A general account of the whole question is given in the book before us, without entering into the necessarily elaborate pure mathematics involved in much of the work on the subject. The last chapter, dealing with conformal representation by means of elliptic functions, was written by Dr. Blaschke, Dr. Lewy having died before his plan was completed. In the present translation, Dr. Jones and Mr. Williams have provided a very readable introduction to the theory of conformal representation. Some matters are discussed in the German text in a descriptive (rather than a scientific) way, but the translation is none the less acceptable on that account. W. E. H. B.

Kolloidchemie der Protoplasmas. Von Prof. Dr. E. Lepeschkin. (Monographien aus dem Gesamtgebiet der Physiologie der Pflanzen und der Tiere, Band 7.) Pp. xi + 228. (Berlin: Julius Springer, 1924.) 9 gold marks.

THE author has catered for the student in a very thorough manner, and devotes the first quarter of the book to a complete survey of the various physico-chemical phenomena associated with colloids, particularly proteins. The colloid chemistry of protoplasm is then developed and discussed from different points of view until finally the author presents a detailed and up-to-date account of the behaviour of protoplasm under the action of physical agents, such as temperature, light, and electricity, and that produced chemically by acids, alkalis, neutral salts, and non-electrolytes. One feels, however, that more might have been made of the effects of low temperatures and particularly of freezing temperatures, including, as it does, not only the temperature factor but also those due to desiccation and probably change in acidity. The book will appeal in particular to the plant physiologist.

There is one very fine plate containing twenty-two microphotographs of several living systems under different conditions, but surely a book of this nature is lacking in having no diagrams whatsoever. It is, nevertheless, well written, covers a wide field, and treats a difficult subject in a most interesting and clear manner.

A Monograph of the Birds of Prey (Order Accipitres). By H. Kirke Swann. Part I. Pp. xi + 52 + 5 plates. (London: Wheldon and Wesley, Ltd., 1924.) 26s. net.

In this monograph, which is being issued in twelve parts, Mr. Swann is bringing up-to-date the results of his recent intensive study of the diurnal birds of prey. In his introduction, which includes a chapter on falconry and hawking, it is stated that he now recognises 322

species and 692 subspecies or forms, while the genera employed number 100. In 1874 Sharpe (Catalogue of the Birds in the British Museum, vol. 1) gave the number of species as 377, but many of these are now considered subspecies. It will therefore be seen that in the last fifty years the number of apparently distinguishable forms has nearly doubled.

Part I. deals with the New World vultures and some of those of the Old World. Each form is separately discussed; its synonymy is given, then its distribution and different plumages in detail, followed by general remarks and notes on food and nesting. We are glad to observe that the status of each species is clearly shown; the typical race is first described; any subspecies bears the same number with the addition of a letter. This arrangement, we think, might with advantage be adopted by modern authors. The changes in nomenclature are many, and are in strict accordance with the rules of priority.

The letterpress and paper are excellent, and the coloured plates, which are by Mr. Gronvold, leave nothing to be desired. We heartily congratulate the author on the production of this work. The edition is limited to 412 copies.

Chemistry in the Service of Man. By Prof. Alexander Findlay. Third edition, revised and enlarged. Pp. xix + 300 + 4 plates. (London: Longmans, Green and Co., 1925.) 6s. net.

PROF. FINDLAY'S book, which has now reached a third edition since its first appearance in 1916, is one of the best accounts of modern chemistry for the lay reader. Unlike many books of this kind, it is written in a dignified style and without insistence on commercialism. The subjects dealt with cover various fields, and the book cannot fail to continue to be popular. It is very suitable for general reading by pupils in higher forms of schools as well as for those older readers who have not specialised in chemistry, since it supplements the ordinary text-books. Three new chapters on radioactivity and atomic structure, on the rare gases of the atmosphere, and on metals and their alloys, have been added in the new edition, and the whole has been revised and brought up-to-date.

The Rare Earths: their Occurrence, Chemistry, and Technology. By Dr. S. I. Levy. Second edition. Pp. xvi + 362. (London: E. Arnold and Co., 1924.) 18s. net.

THE volume under notice is especially characterised by its eminently readable style. The subject is dealt with exhaustively, yet the material is presented in such a way that an honours student could read the whole with profit, whilst the expert will find full references to recent work apart from the detailed treatment in the text. Methods of separation and tests are dealt with as well as the chemical properties of the elements, and the names, occurrence, and composition of the minerals. The book will be welcomed by chemists, and is well printed, and provided with an adequate index. Theoretical considerations of classification and atomic structure are considered, but a just sense of proportion has been preserved. The book contains all the information that the chemist who is not a specialist in this department will require.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Shapes of Birds' Eggs.

ANY notable geometrical symmetry in natural productions invites examination, and among such cases of symmetry the forms of hard-shelled eggs may be included. I remember, on chucking certain eggs in a lathe, being surprised to find that they ran nearly as true as if they had been turned, and there are several points of interest both in respect of the

FIG. 1—Capsule with walls of uniform thickness before and after inflation.

FIG. 2—Capsule with walls of varying thickness before and after inflation.

FIG. 3.—To indicate the relation between the principal stresses and principal radii of curvature in a closed vessel.

close conformity of their shapes to solids of revolution and also in regard to the character of their generating curves.

Symmetry of this kind must have the same sort of origin as that of an inflated balloon, or of the aneurism which forms in an india-rubber tube when the internal pressure exceeds a certain limit.

No doubt the oviduct in which the shell is developed supplies the necessary pressure, whether acting merely as an elastic coat stretched by the growth of the contents, or by actual muscular stress in the non-striated fibres in its walls; the near approach, however, of the transverse sections to true circles implies that the pressure (measured in terms of head) is large compared with any difference of pressure between the upper and lower parts of the egg cavity, for although the pressure of the various parts in external contact with the oviduct must tend to balance the gravitational head in the interior, it is not likely that this balance is at all exact, and, as may easily be shown, small differences of pressure round the periphery of a transverse section would, in the absence of contractive force in the walls, produce comparatively large departures from the circular form.

From the measures given below, I should estimate that the pressure within the oviduct is of the order of a hundred times that given by a column of water of the linear dimensions of the shell. The forms of the generating curve of the solid of revolution must depend either on a variation of thickness in the elastic walls of the oviduct or a variation of muscular stress in its fibres.

This may be illustrated experimentally by the inflation of india-rubber capsules, as shown in Figs. 1 and 2. When the walls are of uniform thickness, inflation produces a sphere; if the cavity is eccentric, on inflation it assumes the egg shape. All the known shapes of eggs can in this way be reproduced by suitably adjusting the thickness of the walls.

The relation of the principal stresses and principal radii of curvature in a shell in which there is internal pressure can be deduced from Fig. 3.

Let the internal pressure be P , and let XX be the axis of revolution of the generating curve of the shell, and $ABCD$ an element of the surface of revolution. Also let $AP (= \rho_M)$ be the meridional radius of curvature and $CO (= \rho_L)$ that of the curvature in latitude. The tension T_M in the shell in the direction of the meridian is equal to $P \times \text{area } BCO - BC \times \text{thickness of the shell } (t)$, and in the direction of the latitude it is $P \times \text{area } ABOO' - AB \times t$. From this statement it can easily be shown that

$$T_M = P \rho_L / 2t \text{ and } T_L = P(2\rho_M\rho_L - \rho_L^2) / \rho_M t;$$

also, since the sum of the radial components of the tension must be equal to P ,

$$P = T_M / \rho_M + T_L / \rho_L,$$

and the ratio of T_L to T_M

$$(2\rho_M - \rho_L) / \rho_M.$$

If the solid of revolution is a cylinder, i.e. if $\rho_M = \infty$, this ratio, as is well known, is 2.

The forms of birds' eggs range from nearly spherical through ovals to bluntly pointed or peg-top shapes, and in this respect are, so far as my observation goes, much more variable than the hard-shelled reptilian or molluscan eggs; but in all cases there is a big and little end, and in laying, the big end comes out first.

A selection of typical forms of birds' eggs is given in Fig. 4. The eggs were placed on a photographic

FIG. 4—Typical forms of birds' eggs.

Figures below are pinhole photographs of the eggs (about one-third natural size). Figures above (drawn to a uniform scale) show the generating curves as dotted lines, and the evolutes in full lines.

plate, vertically under a distant pin-hole, and the definition of the shadow picture is sufficiently good

¹ Since this was written I have been given a reference to a paper by Prof. D'Arcy W. Thompson (NATURE, June 4, 1908) on the shape of eggs. The relations given there between tension and curvature, due apparently to Prof. W. Peddie, are incorrectly stated.

to allow of the determination of the curvature with considerable accuracy

Above each figure (and on a scale which makes the long axis of all the eggs equal in length) is the evolute, which is more characteristic than the generating curve itself. The evolutes were produced by drawing normals to the generating curve at many points round the periphery, and though individual normals might in some instances be not quite correctly drawn, there could be no doubt about the shape of their envelope (*i.e.* the evolute). The ρ_c radii for any given latitude were so nearly constant that their variations could not be satisfactorily determined.

I give below, however, a few measures of the greatest and least equatorial diameters of ostrich eggs (too large to be photographed with the apparatus I was using), for in such large eggs, if anywhere, one might expect to find evidence of gravitational deformation.

OSTRICH EGGS

No.	Locality.	Greatest diameter.	Least diameter	Difference in parts per 1000	Remarks
1	Masailand . .	4 872 in.	4 865 in.	7	
2	"	5 042 "	5 021 "	21	Surface of shell rough.

Science in South Africa.

EVERY man of science will welcome General Smuts' interesting survey, appearing in *NATURE* of August 15, p. 245, of the problems that present themselves for solution in South Africa, for there is no more promising field of research, especially in geophysics.

The great astronomical observatories of the southern hemisphere are no doubt already co-operating in a daily comparison of wireless records and celestial observations, which will render it possible to determine in the course of the next few years whether there is at the present time any relative drift of the land masses of the south.

Not less important is a provision for systematic gravimetric observations, similar to those that have been carried out in the United States, Central Europe, India, and what was German East Africa. If these are sufficiently numerous, they will, in conjunction with the work of the Geological Survey, throw important light on the structure of the earth's crust.

At the same time, a number of seismological observatories should be established. The initial cost of the Milne-Shaw apparatus is comparatively small. As the records must be influenced by the geological structure at and near the receiving station, a careful and systematic comparison of the records at different stations of the same earthquakes should be very valuable.

Observations on the tidal movements and others of similar periods in the earth's crust, such as were made by Hecker at Potsdam, are also needed in South Africa for comparison with those in other parts of the world. They, too, will throw light on crustal structures.

For these and other lines of research South Africa affords unequalled opportunities of obtaining important results, and every one must look forward to see her take a place in the commonwealth of science equal to that of the most advanced of older communities.

JOHN W. EVANS

Transformation of Mercury into Gold.

THE experiments on the transformation of mercury into gold (A. Miethe and H. Stammreich, H. Nagaoka) and the suggested explanation of the process (F. Soddy) lead me to make the following observations. The possibility of the transformation of a nucleus into that of the element next below it by the absorption of one electron is most likely to be detected when both nuclei are stable. This occurs most obviously when the elements have a mass in common, an isobare, and, since even mass-numbers are not found in non-radioactive elements of odd atomic number, an isobare of odd mass-number.

At the present time there is no direct experimental evidence of the existence of isobares of odd mass-number among non-radioactive elements, but there are two cases where the possibility of their existence may be inferred from experimental work. These are the mass-numbers 205 and 199. The existence of the thallium isotope 205 is probable from F. W. Aston's general results for elements of odd atomic number and from the value, 204.4, for the atomic weight. I have given reasons for the existence of the lead isotope 205 (*Phil. Mag.*, 1924, [vi], 48, 365). From the atomic weight of gold, 197.2, it may be inferred that this element has isotopes 197 and 199; mercury, as F. W. Aston has shown, has the isotope 199. There are thus two pairs of elements, lead and thallium, mercury and gold, in which the transformation of the type under discussion may occur. I suggest therefore that the transformation of lead into thallium is as possible as that of mercury into gold, and that the masses of the thallium and the gold produced are 205 and 199 respectively.

There is a possibility that the transformation of lead into thallium by the process under discussion has already occurred in Nature. It has been pointed out by me that when any element of odd atomic number possesses two isotopes, the heavier is never in excess. Thallium did not appear to be an exception to this rule at the time it was made, as its atomic weight was accepted as 204.0 (the masses of its isotopes are assumed to be 203 and 205); it appeared to be one of the elements of odd atomic number like bromine, silver, and antimony, which have isotopes in approximately equal proportions. The new value, 204.4, of thallium's atomic weight, recently obtained, however, makes this element a definite exception. It is possible that the excess of the masses of 205 over those of 203 is the result of a process in Nature of an exceptional kind, for example, of the absorption of an electron by the nucleus of the lead mass 205.

Gibbs' Phenomenon in Fourier's Integrals.

FOURIER'S integral $\frac{1}{\pi} \int_0^x f(\beta) \cos \alpha(\beta - x) d\beta$ is

known, under certain general conditions, to have the value $f(x)$ at a point where $f(x)$ is continuous and $\frac{1}{2}[f(x+0) + f(x-0)]$ at an ordinary point of discontinuity.

It would be natural to expect that the curves

$$y = I_a(x) = \frac{1}{\pi} \int_0^a d\alpha \int_{-\infty}^{\infty} f(\beta) \cos \alpha(\beta - x) d\beta,$$

for large values of a , would tend, in the neighbourhood of $x = 0$, to coincide with the line

$$x = 0, f(-0) \leq y \leq f(+0),$$

when $f(-0) < f(+0)$, the inequalities being reversed when $f(-0) > f(+0)$. However, as we shall now show, this line has to be produced above and below $f(\pm 0)$ by an amount

$$\frac{D}{\pi} \left| \int_{-\pi}^{\pi} \frac{\sin u}{u} du \right|,$$

where $D = |f(+0) - f(-0)|$, i.e. by about 9 per cent. of the jump D . This corresponds exactly to Gibbs' phenomenon in Fourier's series to which attention was directed by Gibbs in NATURE, vol 59, p 606 (1899).

It is sufficient to prove the theorem for a special case from the known properties of Fourier's integral at a point of continuity of the arbitrary function, it can then be extended to the general case.

We take $f(x) = 1$, when $0 < x < l$, and $f(x) = -1$, when $-l < x < 0$, and equal to zero elsewhere: so that $D = 2$ at $x = 0$.

Then it will be seen that

$$\begin{aligned} I_a(x) &= \frac{1}{\pi} \int_0^a d\alpha \left\{ \int_0^l \cos \alpha(\beta - x) d\beta - \int_0^l \cos \alpha(\beta + x) d\beta \right\} \\ &= \frac{1}{\pi} \int_0^l \frac{\sin \alpha(\beta - x)}{\beta - x} d\beta - \frac{1}{\pi} \int_0^l \frac{\sin \alpha(\beta + x)}{\beta + x} d\beta \\ &= \frac{2}{\pi} \int_0^{ax} \frac{\sin u}{u} du - \frac{1}{\pi} \int_{a(l-x)}^{a(l+x)} \frac{\sin u}{u} du \end{aligned}$$

It is easy to show that the second integral tends to zero when a tends to infinity, or, stated more carefully, to the arbitrary positive number ϵ , there correspond positive numbers A and η , such that

$$\left| I_a(x) - \frac{2}{\pi} \int_0^{ax} \frac{\sin u}{u} du \right| < \epsilon, \text{ when } \begin{matrix} a \geq A \\ 0 \leq x \leq \eta \end{matrix}.$$

Now the curve

$$y = \frac{2}{\pi} \int_0^x \frac{\sin u}{u} du \text{ for } x > 0$$

is situated above the axis of x and cuts the line $y = 1$ an infinite number of times. Its maxima occur when $x = \pi, 3\pi, 5\pi, \dots$ and continually diminish, tending to $y = 1$ in the end. Its minima occur when $x = 2\pi, 4\pi, 6\pi, \dots$ and continually increase, tending also in the end to $y = 1$.

Further the curve

$$y = \frac{2}{\pi} \int_0^{ax} \frac{\sin u}{u} du$$

is this curve, with the abscissæ reduced in the ratio $1 : a$. Therefore for large values of a the curve

$$y = I_a(x), \text{ when } x > 0,$$

rises from the origin to a point very nearly coincident with

$$x = 0, y = \frac{2}{\pi} \int_0^{\pi} \frac{\sin u}{u} du = 1 - \frac{2}{\pi} \int_{\pi}^{\infty} \frac{\sin u}{u} du = 1 + \frac{0.56 \dots}{\pi}.$$

A word or two of a historical nature may be added

regarding Gibbs' phenomenon in Fourier's series. As a matter of fact it had been described for the series mentioned by Gibbs in a paper entitled "On a Certain Periodic Function," in the *Camb and Dublin Math. Journal*, vol 3 (1848), by Wilbraham (B.A., Trin. Coll. Camb). To this point my attention was directed some time ago by Prof. G N Watson (see also *Enc. d math. Wissenschaften*, II. A, 12, p. 1049, and II C, 10, p. 1203). Wilbraham's paper seems not to have attracted any notice, and it had been completely forgotten when Gibbs sent his letter to NATURE in 1899.

Du Bois Reymond dealt with the behaviour of the approximation curves for series and integrals in *Math. Annalen*, Bd 7 (1874), in his paper "Über die sprungweisen Werthänderungen analytischer Funktionen." This memoir would have contained an account of Gibbs' phenomenon in both Fourier's series and integrals, if he had not made a curious slip with regard to the possible values of the integral

$\int_0^{nx} \frac{\sin u}{u} du$, when x tends to zero and n to infinity simultaneously.

Prof. Wilton, of Adelaide, noticed the existence of the phenomenon in Fourier's integrals in a paper, "On Gibbs' Phenomenon in Fourier's Series and Integrals" communicated to the *London Math. Society* in 1921. But his argument required further development and this paper has not been published.

The occurrence, or non-occurrence, of the phenomenon in Bessel's and Legendre's series, and in divergent Fourier's series, which can be summed by other means, has been discussed by various writers. It will be interesting to find if analogous results can be obtained in the case of Fourier's integral and other integrals equal to the arbitrary function.

H S CARSLAW.

Sydney, June 16

The Action of Silica on Electrolytes.

FROM Dr. Joseph's letter in NATURE of March 28, p. 460, it appears that our differences are mainly with regard to observation of facts. I therefore describe below the method of preparation of the hydrated silica used in most of our experiments: it was obtained from the hydrolysis of twice-distilled pure silicon tetrachloride. The silicon tetrachloride in the final distillation was collected in a *transparent fused silica flask*. The liquid was hydrolysed in the same vessel, and in the subsequent treatment only fused silica vessels were used. The silica was dried in air at room temperature in a place free from fumes. If Dr. Joseph finds difficulty in preparing the samples, I shall be glad to send him a sufficient quantity for his experiments. I would, however, point out that the silica used by Dr. Joseph differs from ours in one respect in that the silica was heated to 180°. We have found that, on ignition, the adsorptive capacity of hydrated silica diminished markedly, and probably the failure of Dr. Joseph to confirm our results is to be attributed to his having used samples which were "finally dried and heated to 180°."

We would request Dr. Joseph to repeat the following experiment with silica prepared in the manner given above: The silica is washed until the wash water after twenty-four hours' contact shows no opalescence with silver nitrate. It is separated in two equal portions to one of which a definite volume of pure water and to the other a definite volume of saturated solution of potassium nitrate free from chlorides are added respectively. If the two liquids are carefully decanted, the potassium nitrate solution

shows perceptible opalescence with silver nitrate, while the other does not. But if, however, the washing of the silica is carried on for a long time, even after the P_n of the wash water has become equal to that of the water used, the potassium nitrate solution fails to show any trace of a chloride.

Regarding the statement in par. 4 of his letter, I think Dr. Joseph is scarcely doing me justice in suggesting that these obvious precautions were not taken. The silica or the solutions never came in contact with filter papers. Transparent fused silica vessels were mostly used. Where glass vessels were used (resistance glass) it was ascertained that the results were not due to a reaction with the vessel. We have several times repeated and confirmed our observations.

Dr. Joseph says nothing about the increase in the negative charge of the surface at low concentrations of neutral salts, which to my mind definitely proves the primary adsorption of anions, and consequently of electrolytes including acids which contain these anions.

Similar experiments have been done with manganese dioxide, corroborating our point of view. We have communicated a paper to the Journal of the Indian Chemical Society, "On the Nature of Hydrolytic Adsorption, Pt. I," in which the theoretical considerations advanced in previous papers have been developed, and a brief summary of the results obtained in this laboratory during the last four years has also been given. Full experimental results will be published later.

I would take this opportunity to point out that we distinguish between three types of adsorption: (1) primary adsorption, resulting from the chemical affinity of the atoms on the surface (cf. Langmuir), (2) electrical adsorption, and (3) adsorption of solutes (or rather solutions) resulting from the capacity of the substance to adsorb water. The adsorption referred to in my letter in NATURE of April 4 (p. 497) is of the last-mentioned type, and is different from the small amounts of primary adsorption referred to in my letter of January 31.

Gas-pressure, Radiation-pressure, and Entropy in the Interior of a Star.

In the simplest form of Eddington's theory of stellar constitution (*vide* papers in Mon. Not. R. A. S., and *Astrophysical Journal*, 48, 205, 1918), the assumption is made that a certain quantity, β , is constant throughout a given star, β turns out to be the ratio of the gas-pressure to the total pressure (which is the sum of the gas-pressure and the radiation-pressure). The present note shows that the second law of thermodynamics provides a theoretical background for this assumption of Eddington's—justification of which has been largely empirical heretofore.

Write S for the entropy per unit volume at any point within a star, n for the number of molecules per unit volume, dV for a volume-element, and V for the total volume of the star. A feature of Eddington's method is that the volume, V , and the total number of molecules, $\int n dV$ (total mass divided by molecular weight), are supposed—at a certain point in the solution—to be given. Now S may be taken as a function of the two independent variables, V and n . Suppose that the distribution of matter within the star is infinitesimally varied, subject to the two restrictions mentioned; so that

$$\delta V = \delta dV = 0 \quad (1)$$

$$\text{and} \quad \int n dV = 0, \quad (2)$$

where the integrations are performed throughout the entire volume of the star. The condition for stable equilibrium is that the total entropy is a maximum, or

$$\delta \int S dV = 0 \quad (3)$$

In consequence of (1), this is equivalent to

$$\int n \delta S dV = 0 \quad (4)$$

Comparison of (4) and (2) necessitates that

$$\frac{\delta S}{\delta n} = b, \quad (5)$$

a constant throughout V .

It remains to express the relation between b and β . Taking the entropy as that of the radiation alone,

$$S = \frac{4}{3} a T^3 = \frac{4}{3} \frac{p'}{T},$$

where T is the absolute temperature of the elemental region, aT^3 the radiant energy per unit volume; and p' the radiation-pressure. Since the gas-pressure, p , is given by nRT (where R is the gas-constant per molecule),

$$S = \frac{4}{3} n R p' / p \quad (6)$$

Comparing with (5),

$$b = \frac{4}{3} \frac{R p'}{p} = \frac{4}{3} R \frac{1 - \beta}{\beta},$$

and β is constant throughout the star.

This treatment neglects the entropy of the gas. Furthermore, owing to varying ionisation with the varying distributions of matter, (2) above is only an approximation. Consequently the way is left open for more refined theories, according to which β and b may not be constant throughout a given star.

The Experimental Transmission of Cutaneous Leishmaniasis to Man from *Phlebotomus papatasi*.

SERGEANT, ED. et ET, Parrot, L., Donatien, H., and Béguet, M. (C. R. Acad. Sci., vol. 173, No. 21, pp. 1030-1032), first successfully transmitted cutaneous Leishmaniasis to man from sandflies. Their experiment consisted of dividing a batch of 559 sandflies into 23 batches, crushing the sandflies in saline, and inoculating scarified points on the arms of volunteers. The sandflies were caught in Biskra, an endemic centre of cutaneous Leishmaniasis, and the experiment was performed in Algiers, where locally acquired cases of the disease are unknown. One experiment (from a batch of 7 specimens of *Phlebotomus papatasi*) was successful, Leishman-Donovan bodies being found from a papule which appeared 2 months and 24 days after the experiment.

A batch of 198 sandflies (191 *Phlebotomus papatasi*, 16 ♂♂ and 175 ♀♀, 7 *P. minutus*, 1 ♂ and 6 ♀♀) were caught in Jericho on June 25 last, and brought to Jerusalem for dissection. On June 26 a female *Phlebotomus papatasi* was found heavily infected with *Herpetomonas*, flagellates being present in the oesophagus, oesophageal diverticulum, midgut, and hindgut. The alimentary tract contained no trace of blood and the abdomen was full of ripe or almost ripe eggs. A large number of the flagellates were found attached to the under surface of the oesophageal

valve. Only fully developed flagellates were present, and Leishmaniasis form parasites and intermediate forms were not observed. A part of the material was stained and mounted and the remainder was used for the experiment. Two points on the left forearm of a volunteer were scarified and inoculated with material containing flagellates on June 26. On July 31 a small papule which would normally have passed unobserved was noted on one of the inoculated points, and on examination Leishman-Donovan bodies were found, i.e. the incubation period was less than half of that noted by the Sergeants and their collaborators. Nothing was noted on the other site of the inoculation, but it was examined and up to the time of writing has proved negative.

It must be further noted that the insect from which the material for the experiment was obtained was the only one from the batch of 198 which contained *Herpetomonas*.

The method of dissecting individual sandflies and experimenting with a positive individual is more satisfactory than crushing batches in saline and experimenting with the product, for in the latter case it is impossible to know whether a negative result is due to the fact that the sandflies contained no *Herpetomonas* or whether the *Herpetomonas* was non-infective.

For various reasons we do not think that the successful experiment of the Sergeants and collaborators and our own experiment provide a complete explanation of the etiology of cutaneous Leishmaniasis, and we intend to discuss this point elsewhere. It must be pointed out that Patton has on several occasions pointed out the necessity of the experiment performed by the authors (Bull. Soc. Path. Exot., vol. 12, No. 8, pp. 500-504, and *Ind. Jour. Med. Res.*, vol. 9, No. 3, pp. 496-532).

Spiral Springs of Quartz.

MAY I express my interest in your recent correspondence on quartz spiral springs (NATURE, June 20, p. 943, and July 4, p. 14), and suggest a convenient laboratory method for the production of springs of extreme sensitivity. I refer to the use of fibres the diameter of which is 10^{-3} cm. or so.

One end of a length of fibre is weighted and the other attached to a transparent quartz tube by fusion. This is accomplished simply, by heating to incandescence a small portion of the tube in an oxygen flame and quickly lowering the heated spot on to the fibre, which is held at right angles to the axis of the tube. A perfectly strong joint is made and the loaded fibre may be wound up at the desired pitch (difficulties arise owing to air-currents if the tube is not lowered on to the fibre). A similar procedure serves to finish off the spiral: a small portion of the tube, say 1 cm. away from the windings, is heated to incandescence, and, tilting the tube, the last turn of the spiral is wound over the hot spot. The spiral with its supporting tube is now placed axially in a wire wound resistance furnace and heated rapidly in air above the annealing point of fused silica—1 minute at 1100° C. is adequate for a fibre 10^{-3} cm. diameter wound on a diameter of 1 cm. No trouble from devitrification is experienced and the elastic properties of the fibres are unimpaired; moreover, the curvature of the coil is uniform throughout.

Removal is best accomplished by unwinding slightly one of the end turns of the spiral; bending it outwards from the tube and away from the coils. In this position the end may be secured to a rigid

support by any suitable adhesive, the remaining turns being similarly opened and wound off. In this process a single camel hair is useful to guide the motion of the fibre, and is best used without artificial aid to vision. As an example of sensitivity, a spring so made with which I have experimented has an expansion rate of 3×10^6 cm. per gram, this measured by deformation under its own weight.

By careful regulation of the time and temperature of heating, a coil may be made, which, when released at its ends, is of larger diameter than the tube on which it was wound. Incidentally, this technique for producing springs of varying curvature, under specified conditions of time and temperature, offers a very convenient method for the study of the annealing of vitreous bodies, since a simple series of experiments gives quantitative information as to the time rate of the release of strain.

Fish Poisons as Insecticides.

THE destruction of fresh-water fish by means of the poisonous properties of certain plants is almost as widespread as the use of the conventional form of fish trap in one or other of its common modifications. Like the savages of many tropical countries, the poachers of Southern Ireland employ a vegetable fish poison, and this they obtain from spurge (*Euphorbia hibernica*). The primitive method of use is merely to put the freshly gathered plant (leaves, stem, and root) into a sack and tread on this vigorously in the shallow water at the head of a pool. The expressed juices mingle with the water and rapidly render all fish helpless for, it may be, three-quarters of a mile downstream. It is said that affected fish never recover, and the amount of destruction wrought, especially in streams where quantities of salmon parr and small trout exist, can easily be imagined.

The more modern method of application is, I understand, to crush and chop the plant in a chaff cutter or some similar agricultural machine, collect the juice in a bottle, and put this into the stream either with, or without, the chopped-up plant.

If it were found that the spurge poison is also valuable as an insecticide, the plant would probably be more easily obtained, or cultivated, than some of the tropical forms.

Flax water, the scourge of certain rivers in Northern Ireland, is in its effects at least as deadly as spurge, but its effect is due to the product of the decomposition of the softer parts of the flax plant in water and not the juice of the plant itself.

The Word "Australopithecus" and Others.

NEITHER Dr. Bather nor Dr. Allen (NATURE, June 20, p. 947, July 25, p. 135) directs attention to the fact that the names of all well-regulated families or sub-families should be based on a generic name, so that the term *Homosimiidae* is ill advised. As for the name *Australopithecus* and any other combinations, it might be said that scientific names are not, strictly speaking, literature, though so regarded by the orthodox. Many years ago Le Conte, to show that a name need not necessarily mean anything, gave the name *Guyascutus* to a genus of beetle.

Moseley's Work on X-rays.

By SIR ERNEST RUTHERFORD, O.M., F.R.S.

TO the many friends of the late H. G. J. Moseley, who was killed in action at Gallipoli in 1915, it has always been a matter of regret that no reasonable portrait of him could be found. Apparently Moseley had an objection to placing himself in the hands of the professional photographer. Recently, Mr. N. Garrod Thomas kindly sent me the negative of a snapshot of Moseley taken probably in the Balliol-Lincoln Laboratories at Oxford in the summer of 1910, about the time of his graduation and before he took up a post as lecturer in physics in the University of Manchester. A part of this negative has been enlarged by Mr. W. H. Hayles, of the Cavendish Laboratory, and is here reproduced.¹ I think all will agree this is an admirable portrait of Moseley. It is difficult to be certain of the apparatus in his hands, but it may have been connected with a repetition of some of the expansion experiments of Prof. C. T. R. Wilson, which it is known he carried out about that time.

In an obituary notice in this journal (Sept. 9, 1915), and also in a special notice in the Proceedings of the Royal Society in 1916, I gave an account of Moseley's life and work, and directed attention to the fundamental importance of his two papers published in the *Philosophical Magazine* (Dec. 1913, April 1914), entitled "The High Frequency Spectra of the Elements." In these

papers he formulated for the first time the law, now known as Moseley's Law, governing the X-ray spectra of the elements, and by its aid was able to fix definitely the number and order of the elements. While the importance of these brilliant researches was immediately recognised, now that a decade has elapsed we can appreciate even more clearly the significance and fundamental character of his discoveries and can estimate the extent to which his work has influenced the development of modern physics.

In this connexion it may not be inappropriate to recall briefly the theoretical position at the moment Moseley began his investigation and the subsequent developments. The nuclear theory of the atom had

been advanced in 1911, and from the results of experiments on the scattering of α rays, it had been suggested that the nuclear charge of an atom might be given by the atomic or ordinal number of the element. On the nuclear theory, the properties of an atom are defined mainly by its nuclear charge, since this controls the number and arrangement of the outer electrons.

Following the discovery in 1912 by Laue, Friedrich, and Knipping of the diffraction of X-rays by crystals, W. H. and W. L. Bragg in 1913 had found evidence by the electric method of the presence of bright lines in the spectrum of platinum, using the method of reflection of crystal faces. These results were confirmed and extended by an investigation by Moseley and Darwin, published in the same year.

At this stage I remember well a discussion with Moseley, in which he proposed a research to test whether an examination of the X-ray spectra of a group of elements could give a decisive answer to the question whether the properties of an atom are defined by its atomic number, as suggested by the nuclear theory, or by its atomic weight, as indicated by the periodic law of the elements. As we know, his hopes were strikingly verified. He rapidly examined by the photographic method the K spectra of a group of the lighter elements and the L spectra of a number of the heavier elements. The conclusions reached by Moseley are clearly given in the terse summary in his second paper, which for its interest is reproduced here.

1. Every element from aluminium to gold is characterised by an integer N , which determines its X-ray spectrum. Every detail in the spectrum of an element can therefore be predicted from the spectra of its neighbours.

2. This integer N , the atomic number of the element, is identified with the number of units of positive units of electricity contained in the atomic nucleus.

3. The atomic numbers for all elements from Al to Au have been tabulated on the assumption that N for Al is 13.

Henry Gwyn Jeffreys Moseley, 1887-1915.

¹ I have arranged with Mr. Hayles to provide copies of this enlargement at a small charge.

4. The order of the atomic numbers is the same as that of the atomic weights, except where the latter disagrees with the order of the chemical properties.

5. Known elements correspond with all the numbers between 13 and 79 except three. There are here three possible elements still undiscovered.

6. The frequency of any line in the X-ray spectrum is approximately proportional to $A(N-b)^2$, where A and b are constants.

Apart from (2), the conclusions drawn in Moseley's paper are a straightforward interpretation of the experimental facts and involve no theoretical assumption as to the nature of radiation or the structure of the atom.

Moseley's identification of the atomic number as a measure of the nuclear charge afforded an interpretation of the frequency law he had found in accord with Bohr's quantum theory of spectra, which had been published previously. The correctness of this identification has since been verified by Chadwick by direct measurement of the scattering of α rays by the nucleus.

As a result of these brilliant experiments of Moseley, a relation of unexpected simplicity is seen to hold for all the elements. The properties of an atom are defined by a whole number which represents the ordinal or atomic number of the element and, at the same time, its nuclear charge and the number of electrons external to the nucleus. The atomic weight turns out to be in a sense a secondary property and the periodic law of the elements is put on a wider and more philosophical basis by the substitution of the atomic number or nuclear charge for the atomic weight of the atom.

The work of Moseley has formed a solid and indispensable foundation for the subsequent attack by an army of researchers of the great problem of the constitution of the outer atom. His frequency law has proved an invaluable aid in interpreting the intricacies

of X-ray spectra and their relation with atomic constitutions—a subject on which so much fine work has been done in recent years.

We have seen that Moseley showed that all possible elements, disregarding isotopes, had been discovered up to number 79 except three.² numbers 43, 61, and 75, and he stated "as the X-ray spectra of these elements can be confidently predicted, they should not be difficult to find." The study of the X-ray spectra affords a powerful and unique method of chemical analysis of a mixture of elements; subsequent research has shown that the presence of an element can be detected with certainty and its amount estimated by its X-ray spectrum even if it be present only to the extent of one part in a thousand. The first of these missing elements found by this method, namely, number 72, was called hafnium by Hevesy and Coster. In this case the method of X-ray analysis was all-important since hafnium is always found with zirconium, with which it is chemically so closely allied that separation is very difficult.

If the other missing elements existed in appreciable amount in minerals, their detection seemed certain. A few weeks ago it was announced by Dr. Noddack and Fraulein Tacke that the missing elements 43 and 75 had been identified by their X-ray spectra in material separated from certain platinum minerals. A preliminary account of their investigations has been given in this journal of July 11. One element, 61, in the rare earths remains unidentified; but for this, Moseley's list of numbers is complete from 1 to 84.

Moseley had the spirit and courage of the true pioneer in science, coupled with great original ability and powers of work. It is rare in the history of science that so young a man has achieved so much.

² In making this statement, Moseley assumed that number 72 had already been filled by a rare earth element cerium. As we now know, number 72 had not been isolated at the time Moseley wrote. There were not three but four gaps.

Concerning the Rate of Man's Evolution.¹

By SIR ARTHUR KEITH, F.R.S.

BEFORE proceeding to discuss my subject—"The Rate of Man's Evolution"—it may be well to ask the question: Is evolution at work in England to-day? Are the Londoners of to-day taller than those of two, ten, or twenty centuries ago? Any one who sets out to answer this simple question is brought face to face with the difficulties which encompass the inquiries of the student of man's evolution. His difficulties are those of variability. The men and women we meet on the streets are of varying height; to strike a true average for the stature of Londoners we must measure hundreds of individuals in every district of this great city. Nor would our average for London hold for the men and women of Birmingham, Manchester and Newcastle, nor would the averages for these cities hold for their surrounding districts. To know the average stature of men and women now living in England entails the measurement of many thousand individuals.

Until the War we believed that the average Englishman stood 5 ft. 8 in. in height; figures gathered then compel us to reduce our estimate by nearly 2 in. When we search the ancient graveyards and burial-places of

England to ascertain the average stature of the men and women buried in them, our difficulties are even greater. The people buried in ancient tombs differed in height just as much as we do; the numbers available for measurement are limited; we have to estimate stature from the length of their limb bones. If we are uncertain of our modern stature, we are still less certain of that of former times. Still, if for the moment we dispense with the precision of the biometrician, we may say that there has been no great change in the stature of the inhabitants of these islands since the close of the Ice Age, some 12,000 years ago. There have been "ups and downs," but the mean for modern Englishmen of 5 ft. 6 in. may be taken as the pivot on which the scales of stature have been balanced for thousands of years.

When we apply measurement to the size and form of head, and compare the dimensions of modern Englishmen with those of former times, we are again confronted with the perplexities of variability. In the third millennium B.C. the skulls of England were long and narrow. About the beginning of the second millennium the eastern and southern parts were settled by a people with short and wide skulls; in the first millennium,

¹ Discourse delivered at the Royal Institution on Friday, March 6.

probably as a result of a new influx, the long and narrow skull again asserted itself. In Roman times, and more particularly in Saxon times, the long and narrow skull prevailed. Measurements made on living Englishmen lead to the belief that the head-form has changed and is changing—becoming slightly shorter and slightly wider. There is evidence of a similar change in the head-form of the people in Egypt. So far as concerns the brain-capacity of the skull there is no evidence of increase. From the limited data at our disposal we must infer that the people who occupied western Europe at the close of the Ice Age stood distinctly above their successors of to-day in the matter of brain-size.

I have said that in certain details of bodily structure the Egyptians of to-day do differ from the men who built the great pyramids some 5000 years ago. This, however, is not the accepted opinion. Those who maintain that modern man has ceased to evolve cite the similarity between modern and ancient Egyptians to prove their contention. Only ten years ago I was of opinion that the evidence from England led to the same conclusion. My opinion was altered by certain investigations I carried out in 1914-15. I took fifty skulls (twenty-five of men and twenty-five of women) from English graves which were known to be 1000 years old or more; some of them were as ancient as the pyramids. I instituted a minute comparison between these ancient skulls and those of corresponding numbers of men and women who had lived in England during the eighteenth and nineteenth centuries.

The result of this comparison was to convince me that evolution is now at work on our bodies. The chief change is to be seen in the size and shape of the palate; the roof of the mouth tends to become reduced in size and to become narrower. The bony entrance to the nose shows alterations. It tends to become narrower and its lower margin to rise up so as to form a sharp bony sill. The jaws recede and the bony framework of the nose becomes more prominent. The sockets for the eyes become changed in form, the lower margin or sill of the orbit tends to sink downwards in the face, thus increasing the distance between the lower and upper margins of the orbit. At the same time the orbits become narrower from side to side; the breadth across the upper part of the face becomes less. The cheek bones lose their prominence, and there is a tendency for the face to grow narrower and longer.

It may be said that the changes I have described are due to a diminished use of the jaws in modern people, for the jaws form a large and intrinsic part of the face, and any reduction in size and strength in jaws must necessarily alter the whole face. I do not think we can accept a diminished use of the jaws as a true explanation, for this reason. The changes which I have described are confined to about 30 per cent. of the modern population. 70 per cent. show no such change, and yet all live on approximately the same dietary. The cause lies deeper than a mere disuse of jaws, certain stocks and families show these changes to a more marked degree and more frequently than do other stocks and families. Such evidence as I have gathered points to an increasing frequency of these new characters during recent centuries. Apparently evolution makes its conquests in the way just described, progress is made by climbing the scale of percentages.

The result of this investigation took me rather by surprise, for I had been of opinion that men of our type had lived in England for a hundred thousand years or more and retained their essential characters almost unchanged. This belief was founded on a famous discovery made at Galley Hill in 1888. The schoolhouse of Galley Hill occupies a bluff on the southern bank of the Thames, half-way between Dartford and Gravesend. Standing by the schoolhouse we look northwards across the valley to the flat lands of Essex, Tilbury docks, the scene of another famous discovery of ancient human remains, is clearly visible on the far bank of the river. The bluff on which the schoolhouse stands rises 100 feet above the level of the river, between the bluff and the river lies a stretch of marsh fully a mile wide. On the bluff, close by the schoolhouse, is a pit, dug by cement-workers, now disused, but a busy place in 1888. The workmen had exposed a series of beds, consisting of gravel, sand and loam, which extended downwards fully 10 feet below the surface soil. In the lowest bed but one the workmen began to expose parts of a human skeleton; it lay 8 feet below the original surface. At the same level large primitive flint implements had frequently been found. Was the skeleton thus discovered the remains of one who had helped to fabricate these instruments?

Over the skeleton the original beds were seen to be intact, if there had been a burial, these beds should have shown definite signs of having been broken. The workmen and two other observers, who examined the section while some of the bones were still untouched, were convinced that the skeleton had become naturally entombed when the beds of sand and gravel were being formed. As to the man thus brought to light there can be no doubt. I have spent many hours in examining his bones. His skull, jaws and limb bones are marked by certain primitive features, but every one of these can be matched in the skeletons of men who are living in England to-day or have lived in recent times. Galley Hill man was of the modern European type.²

Try as I could I did not see how the geological evidence at Galley Hill could be set aside, and I accepted the inevitable conclusion that Galley Hill man was as old as the strata in which he lay. How old are these strata? They are records of the ancient history of the Thames valley. The river made the valley and wrote its records. The gravel deposits on the bluff at Galley Hill are but a fragment of the terraces which fringe both sides of the valley of the Thames at the 100 feet level. These fringing terraces were laid down in the bed of the river or on the shores of its estuary. They tell of a time when the land on which the older and richer parts of Westminster and London now stand lay fathoms beneath the waters of the estuary, and buried deeply by the deposits which accumulated as tides flowed and ebbed.

Geologists recognise other and later terraces of the Thames valley. There is an extensive series at the 50 feet level. Piccadilly runs along this terrace; the foundations of the Royal Institution penetrate its sands, gravels and loams. There are still later deposits of the 25 feet terrace. The Admiralty Buildings, the Houses of Parliament and the Horse Guards stand on this

² The circumstances of this discovery and the character of the skeleton are described in my "Antiquity of Man," second edition, 1923.

terrace. We find in this terrace deposits which mark the close of the Ice Age in England, a date which geologists regard as about 10,000 or 12,000 years distance from us. It is clear, then, that much has happened in the valley of the Thames since the river began to lay down the deposits which make up the 100 feet terrace. If geologists did think in terms of years, there are few who would limit the history of this period of the Thames valley to a term of 100,000 years; many, I am sure, would demand twice this sum. If Galley Hill man is as old as the deposit in which his bones lie, then the rate of man's evolution has been so slow as to be almost imperceptible.

In recent years a new light has been thrown on the history of the Thames valley by a simple discovery. Women know that every hat and coat is dated by its cut or design; they believe that fashion began her imperious sway in modern times. Archaeologists and geologists groping amongst the dust heaps of the past have found that mankind has always been the slave of fashion. At all times man has shaped his implements according to the prevailing fashion of the place and period. His handiwork is just as datable as are our hats and houses. French archaeologists, when they began to explore their caves methodically some sixty years ago, made this discovery; they began to work out the sequence of fashions. It was soon found that the system discovered in caves could be applied to the deposits or terraces of river valleys. The fashions of the river valleys went a long way further into the past than did those of the caves. The deposits of the 100 feet terrace of the Thames valley, for example, were found to contain fashions of three consecutive periods. For the deepest and oldest bed of all implements were worked in a pre-Chellean manner; in the strata just over the burial bed of Galley Hill man implements were of full Chellean workmanship; in the more superficial strata they were worked in the Acheulean manner. Thus, if we admit that Galley Hill man is truly of the same age as the 100 feet terrace, then his culture is that of Chellean man. The implements of this period often show evidence of high skill in the working of flint.

When the fossil remains of Galley Hill man were discovered, we had only geological data to assist us in fixing their antiquity. Since then a new source of evidence has come to light. In the deposits on the sides of our valley—in the strata of its terraces—there is a complete sequence of the cultural phases of the Pleistocene period. We can trace all the stages which link the cultural debris now being entombed by the Thames in its bed to the pre-Chellean implements which were engulfed when the deepest and oldest stratum of the 100 feet terrace was deposited. Galley Hill man lay in the middle or Chellean strata of that terrace. Those who have studied the sequence of Pleistocene cultures, and have assigned just estimates to each, suppose that the Chellean phase of culture was moving towards its zenith 100,000 years ago. If we base the age of Galley Hill man on cultural evidence, we have to assign to him an antiquity of 100,000 years. If we accept this age, then we have to infer that the type of man now found in Western Europe has come through the greater part of the Pleistocene period without undergoing any great degree of change.

Let us now look at the evidence relating to man's

antiquity which has been accumulating these past years on the continent of Europe. The Neanderthal type of man, which we are to investigate first, belongs to the Mousterian phase of culture, one which is much more recent than the Chellean. Most authorities would date the beginning of the Mousterian phase at about 40,000 B.C., and its concluding phase as about 20,000 B.C. All the graves of this long period—from Gibraltar in the south to the centre of Germany in the north—contain remains of only one type of man, the primitive Neanderthal type. The bones of the modern type—Neanthropic man—are never met with. We must thus conclude that the European of the long Mousterian period was Neanderthal man.

Further, the discoveries made at Ehringsdorf, near Weimar, and in the Mauer sands near Heidelberg, have revealed older and more primitive representatives of the Neanderthal type. Heidelberg man is as old as the deepest bed of the 100 feet terrace of the Thames valley; he belongs to the opening phase of the Pleistocene period. Thus all the evidence from the continent leads us to believe that Europe was inhabited by men of the Neanderthal type throughout the greater part of the Pleistocene period. They underwent a considerable degree of evolution before their type was extinguished at the end of the Mousterian period. There are only two items of evidence which clash with this interpretation—namely, the discovery made at Galley Hill, and another at Clichy, in Paris, where human remains, very similar to those of Galley Hill, were found in a stratum of Chellean date.

All authorities are now agreed that the Mousterian period closed some 20,000 years B.C. with the sudden appearance in Europe of men of the modern type. These forerunners of the modern European were big-brained fellows, in every respect of our own type, save that all of them were strong-jawed and had countenances cast in a somewhat rugged mould. A little toning down of these characters would convert them into modern Europeans. It is clear that these forerunners which broke into Europe at the end of the Mousterian period had evolved elsewhere. We have not yet found their cradle-land. I suspect that it will be found in the northern stretches of the Sahara, or perhaps farther to the east—in Arabia or Southern Turkestan. If only we could discover the prototype of the European and assign a geological date to it, we should settle once and for all whether it was possible for men of the modern type to have made a settlement of Europe during the Chellean period, from which they were afterwards expelled by Neanderthal man, or whether his first appearance in Europe was that made at the end of the Mousterian period, when he conquered and extinguished Neanderthal man. If we accept the first alternative, then the evolution of the European type has been slow; if we accept the second, then it has been more rapid. Circumstances force me towards accepting the latter alternative.

Let us turn for a moment to another representative of mankind at the beginning of the Pleistocene period—Pitldown man. I think we are all agreed that his culture was pre-Chellean, and that his period is represented by the deepest and oldest bed of the 100 feet terrace. He thus belongs to an older and more primitive cultural period than that of Galley Hill man. In

form of skull and in size and pattern of brain, this early representative of Pleistocene humanity does not differ markedly from living races, if not actually on our line of descent, the Piltdown type cannot be far removed from it. The anthropoid characteristics of his jaws and teeth are the chief obstacles to placing the Piltdown type on the direct line of our ancestry. We may presume, however, that our direct ancestor had reached as high a stage at the dawn of the Pleistocene period as that attained by Piltdown man. Even then evolution must work with some rapidity if the modern European is to be produced before the Pleistocene period had closed.

We must also take into consideration that remarkable fossil type of man discovered in Java, to which the name *Pithecanthropus* has been given. We may accept the date ascribed to him by his discoverer, Dr. Dubois, as late Pliocene. He is thus older than either Piltdown man or Heidelberg man. His brain possessed distinctively human features, but it is much smaller, much less evolved than any hitherto ascribed to man. His skull and his brain, so far as we know them, stand midway between the status of ape and man. To transform this ancient type of Java into the most primitive of living human types, evolution would have to proceed at an extremely quick pace. It is easier to believe that *Pithecanthropus* represents the persistence of an early Pliocene type than that it represents the stage reached in human evolution at the end of that period.

The discovery made in the Broken Hill mine, South Rhodesia, in the autumn of 1921, must also be taken into account. Here was brought to light the fossil remains of a primitive human type. Rhodesian man may be described as the cousin of Neanderthal man, but was more primitive in many respects than any example of Neanderthal man so far found in Europe. Neither the geological nor the cultural age of Rhodesian man is fixed as yet, but we shall not over-estimate his antiquity if we make him a contemporary of the men who lived in Europe at the beginning of the Mousterian period. Neanderthal man became extinct, he was not transformed into modern man. In this respect Rhodesian man differs from him, he could stand very well as an ancestor to men of the Australoid type; he might be on the line along which modern races have evolved. To transform the Rhodesian into the Australoid type within the compass of the Pleistocene period demands a moderately rapid progress, to transform the Rhodesian type into that of the modern European in this space of time would require evolution to move at a rapid rate.

The important discovery which Prof. Dart has made at Taung, Bechuanaland, has no bearing on the problem we are discussing here. He has found the fossil remains of a young anthropoid ape; it is akin to the chimpanzee and to the gorilla. This discovery throws light on the history of anthropoid apes and upon their evolutionary proclivities, but not, I think, upon the pedigree of humanity.

I have stated the chief facts on which anthropologists have to base their judgment as to the rate at which man has come by the present characters of his body and brain. We are all agreed as to the primitive nature of the human types discovered at Piltdown, Heidelberg, Java and Rhodesia. There is also a broad agreement as to the early dates at which these types lived. If they represent the general stage which evolving humanity had reached in the opening phase of the Pleistocene period, then we must count that man's ascent to his present place has been one of rapid progress. On the other hand, we have the discoveries at Galley Hill and Clichy. The men found in those instances are of our type; if we accept the geological evidence, we have to presume that, so far as our ancestry is concerned, evolution has been stationary throughout the greater part of the Pleistocene period. As evidence accumulates, it becomes easier to reject the geological evidence relating to the discoveries at Galley Hill and Clichy, and more difficult to believe that man in his full-blown modern form could have been the contemporary of the uncouth types discovered at Piltdown, Heidelberg, Java and Rhodesia. In brief, the evidence which accumulates forces us to the conclusion that the evolution of man has been more rapid than many of us have hitherto believed.

I began by showing how much our anthropological inquiries are complicated by the rank degree of variability which prevails among all races of mankind. The same difficulty confronts us when we set out to search for our Pleistocene ancestry. The world of to-day is populated with races of the most diverse types. It was so in remote times, only the population was then sparse and scattered, and the racial types were infinitely more divergent than they now are. Of the early fossil types so far discovered only one—the Rhodesian man—has any claim to a place in the direct lineage of modern races. The stages which lead on to man of the Indo-European or Caucasian type have not been found as yet. It is not until we have unearthed these missing stages that we shall be in a position to pass a final judgment on the rate of man's evolution.

Current Topics and Events.

ON July 3 a deputation from the Australian National Research Council waited upon the Prime Minister of the Commonwealth to present a strong protest against acquiescence in the annexation by France of the Antarctic territory of Adélie Land, an action which was announced by French Presidential decree on November 24, 1924. On behalf of the Council, Sir David Masson (president) pointed out that since 1840, when d'Urville sighted and named, but did not land upon, Adélie Land, no attention has been given by France to this region. British expeditions, on the other hand, costing money and life, have made

important additions to scientific knowledge of what, from its geographical position, has come to be known as the "Australian Sector." On the Mawson Expedition of 1911-14, which added 1000 miles of coastline to the map, Australia has already spent 70,000/, and elaboration and publication of valuable results is still in progress. To no other country will further investigation of this sector be of such interest and significance. The progress of meteorological science, for example, will probably make the establishment of observing stations exceedingly important for Australia, for it must be remembered that Adélie Land, due

south of Adelaide, is nearer to Hobart (1467 nautical miles) than Hobart is to Perth. Economically, too, these lands must become of great value, and the framing and administering of laws regulating the exploitation of seals, whales, and other life in the neighbouring seas are matters urgently requiring attention. The question is whether France or Australia is the proper authority to take the required action.

THERE being no accepted international law in the matter of the administration of unclaimed polar territory, the Australian National Research Council urged the adoption of the principle applied by Canada in 1886 to Arctic lands. In effect this is that unclaimed polar lands should be administered by the most closely adjacent civilised Government. The assignment to Canada of the area between it and the Pole lying between the Canadian E. and W meridians of longitude, to Norway of Spitsbergen, and to Russia of Wrangel Island, are all in accord with the principle. So was the establishment of the Falkland Islands Dependency in the Antarctic under British rule, and of the Ross Dependency under New Zealand (July 30, 1923). It is now proposed that Australia should claim international sanction for the administration of the whole of that part of the Antarctic continent between 90° E. and 160° E., and it was pointed out on behalf of the deputation to the Prime Minister of the Commonwealth that, on the same principle, France would be justified in claiming an area lying to the south of her various island possessions in the southern hemisphere. The whole matter is arousing considerable interest in Australia, particularly in scientific circles, and it is hoped that the result of Government inquiries and action will be a friendly solution of the difficulty in accordance with the Canadian principle.

THE extending use of electricity in agriculture abroad has turned the attention of many supply engineers in Great Britain to the investigation of its possibilities, and a report on the subject has been published in the August Journal of the Institution of Electrical Engineers. The conditions which lead to an economic use of electrical power in farming are different in various countries. In Sweden, for example, the transmission lines from the waterfalls pass along the valleys in which the agricultural areas are situated. In this case, the lines can be readily tapped and the farmers supplied at a low price. In Holland, many lines are in existence traversing agricultural land on their way to supply towns or the electric pumps used for drainage purposes. In Switzerland also, the lines supplying the semi-domestic factories can be readily tapped. In France, however, the shortage of man power makes it necessary to use electric power, and military reasons make it advisable to maintain the agricultural areas at their maximum efficiency and make them as attractive as possible to the population, even at the expense of the State. In Italy, there is a superabundance of hydraulic power from the Alps in the summer time when the industrial demand is a mini-

mum and the farming demand is a maximum. Financial assistance is given by the State to rural distribution lines in Italy, Canada, and Scandinavia. In some of the districts abroad the supply is remunerative and some progress has been made in Great Britain. Most electrical engineers believe that the electrical equipment of all our main line railways is merely a question of time. When it is accomplished, there will be many distribution systems in existence from which a supply to agricultural areas could easily be given at remunerative rates. The cost of an overhead system to supply farmers is about 500/ per mile; this is mainly due to strict government regulations. In Sweden the cost is sometimes so low as 100/ per mile. It looks as if we would have to wait until the advent of electric traction before much progress can be made in applying electricity for the benefit of British agriculture.

THE opening meetings of the fifth Congress of the French Society of Chemical Industry will be held at Paris in the second week in October. As part of the proceedings, a special assembly will commemorate, on October 11, the one hundredth anniversary of the practical establishment of the soap industry by the French chemist, Michel Eugène Chevreul, who, in 1825, with J. L. Gay-Lussac, started a factory for the manufacture of stearic acid. Through his prolonged scientific researches Chevreul explained the process of saponification. The President of the French Republic, members of the Academy of Sciences, and those of kindred bodies will join in the forthcoming commemorative session. Born at Angers on August 31, 1786, Chevreul died in 1889, at the age of one hundred and three years. At seventeen Chevreul went to Paris, entering Vauquelin's chemical manufactory, ultimately he became director there of the laboratory. Later (1824) he took up the post of Director of the Dyeing Department and professor of dyeing at the tapestry works of the Gobelins. His well-known researches on the principles of harmony and contrast of colours were carried out at this period. In 1864 Chevreul was appointed Director of the Museum at the Jardin des Plantes, retiring in 1879. Elected a foreign member of the Royal Society in 1826, Chevreul was awarded the Copley Medal in 1857. The centenary of the birth of this distinguished chemist was celebrated in Paris with signal honour and many felicitous demonstrations. A great procession to the cathedral of Notre Dame took place on the occasion of Chevreul's funeral in 1889.

ACCORDING to a message dated August 24 in the *Times*, Capt. Amundsen's ship, the *Maud*, has returned to Nome, Alaska, in charge of Capt. Visting. It will be remembered that Capt. Amundsen set out in June 1922 with the *Maud*, intending to fly from Wainwright or Point Barrow, Alaska, across the Pole to Spitsbergen, and leaving the *Maud* to drift across the polar basin in the ice. Early in 1923 the position of the *Maud* was reported as lat 74° N, long 170° 30' E., and the most northerly point recorded is now stated to be lat 77° N, long 146° W. North-westerly cross-currents prevented the ship from

drifting across the polar basin. The party found that polar bears were numerous. As is now well known, Capt. Amundsen changed his plans for the polar flight and set out from Spitsbergen in May last, returning there on June 18 after having reached lat $87^{\circ} 44' N$, long. $10^{\circ} 20' W$.

WE welcome the appearance of a new German anthropological publication—*Zeitschrift für Völkerpsychologie*—which revives the title of a publication now defunct. It is edited by Dr. Richard Thurnwald, the well-known field worker and a sociologist of acknowledged merit. One of the objects of the new journal is to keep anthropologists in other countries, especially in England and in the United States of America, in touch with the latest results of continental work. It is even hinted that should the number of readers in England and the United States be sufficient, papers and reviews in English will be included in the contents. As an earnest of its international aim it may be mentioned that the editorial staff includes Dr. Malinowski, who is reader in social anthropology at the London School of Economics and Political Science, University of London. Should it be possible for the policy outlined by its editors to be carried out, the *Zeitschrift* should fill a serious gap. The loss by Germany of her colonies has brought about a serious curtailment of the sum total of the opportunities for and encouragement of anthropological research, which was a prominent feature in German public policy. The several annual expeditions fitted out by the Kolonialamt have necessarily ceased, and the publication of the *Mitteilungen aus den Deutschschutzbereichen*, the activities and publications of the Hamburg Institute, as well as of the many museums in the principal cities are now no more, or exist only in an attenuated form. It is not without misgivings that the British anthropologist views the disappearance in those territories now mandated of the official or officially encouraged study of the primitive populations. In this respect, however, the mandated territories are, unfortunately, in no different case from most of the dependencies of the British empire.

THE thirteenth annual meeting of the Indian Science Congress will be held in Bombay on January 4-9 next. Sir Leslie Wilson, Governor of Bombay, has consented to be patron of the meeting, and Mr. A. Howard, Director of the Institute of Plant Industry, Indore, will be president. The Congress will meet in nine sections, dealing with agriculture, mathematics and physics, chemistry, zoology, botany, geology, anthropology, medical and veterinary research, and psychology respectively. Papers to be presented at the meeting should be forwarded to the general secretary, S. P. Agharkar, 35 Ballyganj Circular Road, Calcutta, or to the president of the appropriate section, with a short abstract, not later than October 15, for submission to the Sectional Publication Committees, not more than ten minutes will be allowed for the reading of any paper. The local secretaries for meeting will be Prof. G. R. Paranjape, professor of physics, Royal Institute

of Science, and Principal A. J. Turner, Victoria Jubilee Technical Institute, P.O. Matunga, Bombay, to whom all inquiries as to accommodation should be addressed.

THE Soviet of Commissars of the U.S.S.R. decided on July 28 that, for all foreign visitors invited to the celebration of the bicentenary of the Russian Academy of Sciences, arrangements should be made for free travel on all the railways and waterways of the Union, for sleeping-cars on the direct communication routes, for seats, and for first-class cabin accommodation on all the sea and river steamers from August 15 until October 1. These facilities will depend on the production of a foreign passport, with the visa of the plenipotentiary representatives of the Union abroad, or of the general consulates of the U.S.S.R., with the inscription, "For the celebration of the Academy of Sciences." Besides free travel facilities, the production of a passport and visa thus inscribed will also obtain, without waiting, reserved seats in express trains, and luggage transport. These passports will thus be considered in the present case equal to the yearly certificates of members of the Central Executive Committee of the U.S.S.R. Special Reception Committees at the frontier stations (including Odessa) will meet foreign guests proceeding to the celebration as soon as they disembark, and assist in getting the necessary tickets or reserved seats without delay.

THE death on July 29, at the age of eighty-seven years, is announced of Prof. H. Hildebrand Hildebrandsson, the distinguished meteorologist who was formerly Director of the Meteorological Observatory at the University of Upsala.

WE much regret to announce the death on August 20, at the age of seventy-nine years, of the Right Hon. Sir George D. Taubman Goldie, K.C.M.G., F.R.S., who may be rightly regarded as the founder of Nigeria. When quite a young man, Goldie travelled extensively in Africa, and in 1877 visited the middle and lower Niger, where British traders had already secured a somewhat precarious foothold, depending on the caprice of the river chieftains. Goldie realised quickly the potential value of the region, and set to work to develop a system of government which would afford peace and security for both natives and traders, consideration of native rights being prominent, as in all Goldie's dealings with the negroes. By 1879 he had amalgamated the trading companies on the Niger into a single company, and two years later he applied unsuccessfully to the British Government for a charter which would have given the company practically sovereign powers. Goldie pursued his course in spite of this set-back, buying out in 1884 some French companies which had established themselves on the Niger. His efforts were rewarded in 1886, when the Niger Company was established, with Lord Abderare as governor and Goldie as vice-governor, after some four hundred political treaties with native chieftains had been concluded. Goldie's schemes were opposed to the aims of the German Colonial Society, backed by Prince Bismarck; but

British interests prevailed, and in 1898 Nigeria was secured to Britain. In 1900 the administration was taken over from the Niger Company by the Imperial Government, and Sir George Goldie took no further share in the administration of the country. Sir George was president of the Royal Geographical Society from 1905 until 1908, and was elected a fellow of the Royal Society in 1902.

THE June issue of the *Journal of the American Museum of Natural History*, New York, affords a good example of the means by which the Museum keeps in touch with its 8000 members, who receive the *Journal* bi-monthly as one of their privileges of membership. Of the nine articles, each of about ten or twelve pages, we have space to refer only to three or four. Prof. Ulric Dahlgren describes in clear, non-technical language the "ear" of a katydid situated in the tibia of the front leg, the structure of the tympana on which the sound waves impinge, and the nervous elements by which the impression is transmitted towards the brain. An article by the glass modeller of the Museum, H. O. Mueller, gives the reader a fair idea of the stages in the preparation of models of rotifers and Utricularia which are excellent examples of his technique. Dr. E. W. Gudger brings together a number of instances of spiders attacking and feeding upon fishes, frogs, lizards, birds, and small mammals, and Dr. W. G. van Name in "an instance where evolution has turned backward" gives a readable account of ascidians. The illustrations are, as is usual in the *Journal*, beautifully reproduced, and include a series by Dr. R. W. Miner representing some of the groups of invertebrates exhibited in the Darwin Hall of the Museum, e.g., as seen on the sea bottom in Vineyard Sound, in a tide pool, on wharf piles, and in sand.

THE Geological Survey of the Union of South Africa has just issued *Memoir No. 19* on the Inland Coalfields of Natal, by W. J. Wybergh. This memoir describes the three important coalfields of Natal, the Klip River coalfield, the Vryheid coalfield, and the Utrecht coalfield, giving descriptions in each case of the general surface contours, of the geology of the field, the general analyses and commercial qualities of the coal of the various seams, and finally an attempt to estimate in each case the available coal reserves. The available information concerning the three fields differs considerably, the first named having been quite largely worked and relatively well explored, whilst very little has as yet been done upon the last of the three, although this may well prove to be the most extensive of any. The memoir is illustrated by sketch sections and maps, and constitutes the most complete source of information respecting Natal coalfields which has hitherto been published.

THE Report of the Survey of India for 1923-24 records a considerable increase in the topographical survey of the year, 65,673 square miles being surveyed, an increase of some four thousand square miles compared with the previous year. About 41 per cent of the whole topographical survey has now been

completed. Aero-photo surveys were undertaken in the Irawadi delta and in Waziristan. During the year, 187 one-inch topographical sheets were published, and it has now been decided to treat this series as the tactical map of India, in place of the half-inch series. One new sheet of the international "one million" map was published, making 13 sheets now available. Of the useful maps of India and adjacent countries on the one-million scale, no new sheets were published during the year. Two new sheets have appeared in the Southern Asia series, on a scale of one to two million. The report contains full indexes to all the survey maps.

THE British Museum has recently issued a guide (price 1s.) to the collection of fossil plants in Gallery X in the Department of Geology and Palæontology. This guide, which was originally drawn up by Mr. H. Hamshaw Thomas just before the War, has now been revised by Mr. W. N. Edwards, assistant in the Museum, and with its 6 plates, folding-chart of geological strata, and 70 pages of letterpress with 40 text figures, must be regarded as very good value. The guide is simply and concisely written, and concentrates attention mainly upon features which can be seen in plant impressions and without reference to the microscope, though important efforts at reconstruction of long extinct plant types from the scattered material in the rocks are elucidated with the aid of diagrams, some new, some already well known to the student. It may be hoped that this guide will make more accessible, and therefore better known, the palæobotanical resources of the Museum, which include more than 5500 microscope slides from the historic collections of two English investigators, W. C. Williamson and Dr. D. H. Scott.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: Secretary to the Medical Society of London—The Acting Secretary to the Society, 11 Chandos Street, W. 1 (September 4). Inspectors under the Ministry of Agriculture and Fisheries for the purposes of the Diseases of Animals Acts, 1894 to 1922—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S. W. 1 (September 7). Two analysts for the building research station of the Department of Scientific and Industrial Research—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S. W. 1 (September 14). A junior assistant physicist at the building research station of the Department of Scientific and Industrial Research—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S. W. 1 (September 14). A preparator in the herbarium of the Royal Botanic Gardens, Kew—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S. W. 1. A pathological laboratory assistant in the Agricultural Department of the Government of Kenya—The Crown Agents for the Colonies, 4 Millbank, S. W. 1 (quoting M/13369). A lecturer in entomology, botany, etc., at the Royal Agricultural College, Cirencester—The Secretary

Research Items.

A MAGDALENIAN STATION IN SWITZERLAND—Dr Fritz Sarasin and Dr. H. G. Stehlen describe in the *Denkschriften der Schweizerischen Naturforschenden Gesellschaft*, Bd. 61, the results of explorations of a Magdalenian rock shelter at Ettingen near Basel, undertaken in 1918, 1919 and 1922. The latter deals with the animal remains, the former gives an account of the excavations and describes the archaeological finds. The uppermost stratum consisted of 1.20 to 1.40 metres of brown earth in which were fragments of human bones, bones of recent animals and potsherds belonging to recent, Roman and neolithic times, but no flint implements. The stratum immediately beneath contained no traces of human occupation, but remains of Magdalenian type were found in the two strata below, the first flint implements occurring in the upper of these two strata at depths of 2.50 to 2.70 metres. The implementiferous deposit continued into the lower stratum, the total depth of the deposit being about 50 cm. at its maximum. The implements found included a number of knives and spear-heads of flint, a doubtful implement of limestone, and an implement made from a long bone, 50 mm long with a spatulate-shaped end.

THE AGE OF THE PADMA—Vol. 20, No. 1 of the *Journal of the Asiatic Society of Bengal* contains an interesting note by Bisvesvar Bhattacharyya on the date at which the waters of the Ganges, which it is known originally flowed to the sea through the channel now indicated by the Bhāgirathi, the Hoogly and the Tolly's nullah, were diverted eastward into what is now the Padma. It is usually assumed that this was caused by a diversion in the course of some northern rivers which took place about the sixteenth century. References in Bengal literature, however, support an earlier date. Thus a copper plate inscription of Srichandra Deva from South Faridpur recording a grant of land shows that in the tenth-eleventh centuries the Padma flowed through that district but not as a considerable stream, while from a poem by Dhoyi, who flourished in the twelfth century, it may be inferred that the Bhāghurati was then a mighty river. In a poem believed to be of the fifteenth century—the *Rāmāyaṇa* of Kṛttivasa—there is a legend recording that a sacred goddess was taken away through the Padma and brought back through the Bhāgirati, which may be a traditional reference to the diversion of the waters of the sacred stream. The Vaisṇava literature shows that by the end of the fifteenth century the position of the Bhāgirati as an important river had gone. It would appear, therefore, that the diversion of the waters to the Padma must have taken place in the fourteenth if not in the thirteenth century.

GROWTH AND SPAWNING OF SALMON—Mr. W. L. Calderwood has given data on the growth of the salmon (*Proc. R. Soc., Edin.*, vol. 45, No. 13, 1925). He emphasises the great amount of growth which takes place during the first summer of sea-feeding, often continued during the second summer in the sea. Two years commonly elapse before the first seaward migration of the smolt, and such a fish, after spending a year and a varying number of months in the sea, has grown to about three times what its length was when a smolt, and now as a grilse it returns to the river. Other fish have spent two or three years in the sea; these, with two years of early life in the river, are therefore five years old; and still others have spent a further year in the sea, and, not having lost weight by leaving their feeding grounds and spawning, they are of great size. Mr. Calderwood states that all fish more than 50 lb weight are males, and that during his twenty-five years' experience of Scottish salmon fisheries, he has known only two cases of

females more than 40 lb in weight, and both fish came from the river Lochy, one weighed 43 lb. and the other 48 lb. He asks why it is that the salmon which enter the streams of outlying islands, e.g. Lewis, Mull, Skye, and those of small and rocky catchment areas on the mainland are always small, and suggests that it is because of the poor river-feeding for the parr and smolts in those barren grounds. Another feature of the salmon of these small Highland streams is that they return to spawn more frequently than do the fish of the larger rivers. In the river Add in Argyll, fish have been found with three and four spawning marks, and one kelt showed four spawning marks and therefore had spawned five times, which appears to be a unique case. Of all the salmon scales examined by various investigators, only eight which show four spawning marks are recorded—two from the St. Lawrence, four from the Add, one from the Conon, and one from Loch Maree.

CLYDE PLANKTON—Miss S. M. Marshall has studied the plankton of the Clyde for the years 1923 and 1924, and has summarised the principal results (*Proc. R. Soc., Edin.*, vol. 45, No. 12, 1925). The general course of events was the same in both years and is similar to that found at other stations. There is a winter minimum followed in early spring by a large increase in the number of diatoms and of larval forms, e.g. of copepods, cirripedes, and molluscs. This is followed in May and June by a period poor in diatoms but rich in crustacea. July, August, and September are the months richest in variety—diatoms are abundant, peridinians reach their maximum, larvae of all kinds are numerous, as are also medusæ and sagitta. The autumnal diatom maximum is in August or September, after which the number and variety of planktonic organisms decrease. The first part of the paper deals with the organisms in systematic sequence, noting their relative abundance at various seasons, while the second part is a summary of the plankton month by month in 1923.

THE SANTA BARBARA EARTHQUAKE—A short article on the Santa Barbara earthquake by Dr. Bailey Willis, the well-known student of Californian earthquakes, is published in *Science* for July 10. Dr. Willis was in Santa Barbara when the earthquake occurred, and states that it was a moderately severe, but not a very severe, earthquake. That it was much slighter than the Montana earthquake which occurred thirty-six hours earlier is clear from the fact that it was felt in only four counties in California, while the Montana earthquake disturbed four States. The Santa Barbara earthquake, Dr. Willis considers, was due to a movement of a fault that runs along the Santa Inez range of mountains, the movement being from south to north. As each of the four great faults of southern California has produced an earthquake during the last seven years, and as the last great earthquake of the Santa Barbara region occurred in 1857, an earthquake there was expected by American seismologists, and the prevailing feeling seems to be one of relief that it was not more serious. It was known that a strong pressure is being exerted against the Santa Inez range from the south, as Gaviota Peak, a triangulation point of the U.S. Coast and Geodetic Survey, has been thrust 24 feet northward in thirty years.

RIVER GAUGING—A pamphlet entitled "River Gauging" has recently been issued by the Department of Scientific and Industrial Research, being a Report by Dr. M. A. Hogan on methods and appliances for use in Great Britain (London: H.M. Stationery Office, 1925, 2s. 6d. net). As a review of the present state of knowledge on a complex and difficult operation, the publication is an exceedingly interest-

ing and serviceable compilation. It was prepared for the Committee on Gauging of Rivers and Tidal Currents, and the conclusions arrived at are endorsed by them and embodied in their report. Very briefly, the general conclusion is that methods and instruments for gauging are available and adequate for the needs of a hydrometric survey. In detail, for gauging small streams, some form of measuring weir is suggested with an automatic recorder. For large streams with natural flow, the discharge can be expressed as a function of the water level, provided the bed of the river does not alter its character; the curve representing this function in any given case can be drawn from measurements of the discharge by a current meter—this is known as the "stage-discharge" curve. For large streams artificially regulated, the stage-discharge method is useless, but measurements can be made by calibrating a weir by a combination of model experiments and current meter measurements. The most generally useful type of meter on the market is stated to be the small Price meter, as used in the United States. This meter has proved reliable and convenient where the velocity of flow is not less than half a foot per second and there is no undue turbulence. "Where turbulence exists," it is advisable to take readings both by the Price and screw type meters. "Under turbulent conditions," a propeller meter with a guard ring, such as the Stoppani, should be used, as this type is subject only to small error when measuring oblique velocities.

ATMOSPHERIC POLLUTION.—The tenth report of the Advisory Committee on Atmospheric Pollution which has recently been issued by the Meteorological Office, Air Ministry, shows continued activity on the part of this body during the financial year 1923-24. The report is divided into eight sections, three of which deal with methods of measurement of atmospheric pollution which have now become well established. These are: (1) the standard collecting gauge which measures the impurities brought down by rain, (2) the automatic filter which gives a semi-continuous record of the amount of impurity in the air, and (3) the dust counter. The remaining five sections are devoted to more recent developments of the work. Of these, the research into the effect of atmospheric pollution upon visibility is drawing to a close. A close connexion has been found between the amount of impurity as measured either by the automatic filter or by the dust counter and the percentage transmission of light through 50 feet of air. It is probable that the relationship would be even closer were it not for the presence of small water drops in the air in foggy weather. These drops affect the visibility but not the pollution measurements, and no satisfactory means of measuring their number has yet been found. Some useful measurements of dust in the upper atmosphere taken on aeroplanes are recorded from America, but it has not yet been found possible to obtain records in Great Britain, though it is hoped the difficulties in the way may be surmounted shortly. In two other sections a new dust counter for use in exceptionally dusty atmospheres is described, and the darkness of January 23, 1924, in London, when a high fog of unusual intensity prevailed, is discussed in some detail. It is noted that records from one or two additional standard collecting gauges are still needed in country districts, though urban areas are well represented. It may be hoped that this need will soon be met.

WEATHER AT FALMOUTH.—Meteorological notes and tables for the year 1924 prepared by Mr. J. B. Phillips, superintendent of the Falmouth Observatory,

have just been issued. Many features of general interest have been brought out in the notes by the author. Temperature comparisons are made with other stations reporting to the Air Ministry which show Falmouth to enjoy a generally mild winter. The mean air temperature for the year was $51^{\circ} \cdot 2$ F., which is $0^{\circ} \cdot 5$ warmer than the normal for 50 years; the coldest month was February with a mean $41^{\circ} \cdot 5$, the warmest, July with $59^{\circ} \cdot 5$. The absolutely highest temperature was 69° in August, and the lowest 27° in February. The duration of bright sunshine in 1924 was 1597 hours, which is 156 hours less than the normal for 40 years; the brightest month was July with 208 hours, and the months with least sunshine were January and December with 59 and 60 hours respectively. There was a great preponderance of winds from south and west, these directions occurring on 238 days, while north and east winds blew only on 128 days. The total rainfall for the year was 58.08 inches.

CINEMATOGRAPHY IN COLOURS.—The Keller-Dorian method of cinematography in colours is described by M. A. Troller in *La Nature* of August 1. A colour filter is inserted between the components of the lens, which is divided into two equal segments with a parallel-sided strip between them, each of the three spaces thus provided being coloured with one of the three primary colours. The film has impressed upon the back of it closely packed lens-like projections, at the rate of about thirty to forty to the mm., and this side is turned towards the lens, so that each of the lenticular projections on the film gives a minute image of the tricoloured filter on the sensitive surface. For projection the arrangement is the same, but the direction of the light is reversed. To produce the projections on the back of the film, a skilled engraver working under a microscope cuts an original, and from this a suitable steel roller is prepared, which is mounted with an ebonite roller, so that the film may be passed between them. The steel roller is electrically heated to 100° C. to soften the base of the film, and enable it to take the impression.

XENON HYDRATE.—A hydrate of argon was discovered by P. Villard in 1896, and M. R. de Forcrand announces in *C.R. Acad. Sci.*, Paris, July 6, that he has prepared xenon hydrate by compressing the gas, with a trace of water, in a Cailletet apparatus. He had already found a crystalline hydrate of krypton, with the probable formula $Kr + 5H_2O$, in 1923; but the xenon hydrate is produced much more easily, only a few atmospheres being required to coat the walls of the tube with a kind of hoar frost, without the application of ice. At temperatures in the neighbourhood of 0° C., this remains intact when the pressure is only a little above that of the atmosphere. A table gives the heat of formation, starting with liquid water, at a series of temperatures and pressures ranging from 14° C. and 1.45 atm. up to $23^{\circ} \cdot 5$ and 17.00 atm., the mean value being 18.266. At and above 24° C. the hydrate is not formed even with very high pressure; the corresponding temperature for krypton is 13° . It is found graphically that the dissociation pressure of one atmosphere corresponds to a temperature of -0.13° . The calculated number of molecules of water to one atom of xenon is 6.6, that is to say, that there are 6 or 7 molecules of water in the hydrate. The dissociation pressures at 0° C. are 1.15 atm. for xenon, 1.45 for krypton, and 98.5 for argon, a hydrate of neon has not been obtained even with 260 atm. at 0° C. Thus the stability of the hydrate increases with the molecular weight of the gas, and this is also shown by the heats of formation of the hydrates.

Carnot's Cycle and Efficiency of Heat-Engines.¹

CARNOT laid down the great and incontrovertible principle that if, when we have obtained motive power by the application of heat, we inquire whether we have obtained the maximum of motive power from this application, we can answer this question by ascertaining whether by applying the same amount of motive power in reversing the process of expansion, or expansion and contraction, in the course of which we have obtained motive power, we can bring the working substance back to its starting-point. When the process is reversible in this manner, we have obtained the maximum possible output in motive power, whatever be the nature of the working substance, gaseous, liquid, or solid.

Carnot thus furnished a criterion by applying which we could judge of the efficiency of a heat-engine. Unfortunately, however, he failed in applying that criterion correctly. His unsuccessful attempt was, however, a great one, since it has continued to mislead scientific men, and confuse engineers, for now more than a century. Carnot invented the famous Carnot cycle, the bugbear of generations of students, and with it an argument to the effect that it is the most efficient cycle possible in the mode of action of a heat-engine.

It is evident that in the cycle described by Carnot, much of the heat taken up from the source in the second stage (isothermal expansion) is thrown away into the condenser in the fourth stage (isothermal compression). This is apparently a waste of heat energy. It is only in the second and third stages of the cycle (namely, isothermal expansion and adiabatic expansion) that work is done on the engine, or motive power is, to quote Carnot's expression, gained. It is, therefore, at the end of stage three that we must apply Carnot's test. When we do so, and simply re-compress the air to its starting volume, we find that much more work has to be done on the air than was done by it during the second and third stages of the cycle. We have, therefore, in stages two and three of the Carnot cycle expended heat which could have been converted more completely into mechanical energy if we had employed adiabatic expansion; and this waste has evidently occurred in the isothermal stage of expansion, since the third stage is in each case adiabatic.

We thus see that the Carnot cycle is radically inefficient. A great deal of heat is transferred quite uselessly from the source to the condenser, and thus wasted. To obtain from the heat communicated to the air in the cylinder the maximum of work on the engine during the expansion, we must quite evidently make the whole expansion adiabatic, while to reduce to a minimum the corresponding work done by the engine in the compression stage, we must make the whole of the compression isothermal, thus throwing away as much heat as we can with the condenser at its existing temperature.

It is evident that by eliminating altogether the effects of atmospheric pressure, we could at once obtain fifty per cent. efficiency in the cycle of an ideal heat-engine. This is accomplished in the ideal cycle of a steam-engine working with complete adiabatic expansion of the steam down to the pressure of the aqueous vapour in the condenser. In this case the cylinder would be enclosed above, and would contain at the start nothing but aqueous vapour at the pressure corresponding to atmospheric temperature, except for a little water in the space below the piston.

In stage 1 the water would be evaporated before the piston was allowed to move. In stage 2 the steam would expand adiabatically, doing work on the engine, until it reached the pressure of the aqueous vapour above the piston. In stage 3 the piston would return to its original position without any net work being done by or on the engine, and the steam not already condensed would condense again to water. Half the heat applied would be spent almost entirely on the engine during expansion, and the other half would pass into the condenser as the piston returned. The efficiency would thus be practically fifty per cent.

We can see now that the percentage efficiency of a heat-engine, or at any rate of a steam-engine, provided that the expansion is adiabatic and complete, and the compression isothermal, does not depend at all on the difference between the initial and final temperature during the expansion. We can quite evidently obtain just the same percentage efficiency with a small as with a great difference of temperature. On this point we are running counter to cherished academic doctrines and to authority which has been generally accepted for more than seventy years, but that authority rests upon the quite mistaken conclusion that the Carnot cycle is one of maximum efficiency within a given interval of temperature.

Let us now look more carefully, and at the same time from a wider point of view, at the reason why more than fifty per cent. efficiency is impossible in a heat-engine. In the case of the air-engine starting from atmospheric pressure and temperature, it is the atmospheric pressure which limits the stage of expansion. The air can no longer expand and do external work after its pressure has fallen to that of the atmosphere pressing on the upper side of the piston. Now the pressure of the expanding air falls in accordance with Boyle's law in proportion to its relative increase of volume, but the work done during adiabatic expansion, and consequently the fall in absolute temperature of the expanding gas, depends also on the pressure, and therefore proceeds also in proportion to the relative increase in volume. The air in the cylinder can only exist in the expanded state at the existing pressure in virtue of an increase of absolute temperature proportional to the increased volume. This follows from Charles's law. Hence, assuming Charles's law, for every degree of temperature lost by the air in expansion, the air in the cylinder must be a corresponding degree above the atmospheric temperature which it had before heat was applied to it. When the temperature of the expanding gas has fallen by half the amount to which it had been raised, this condition is no longer possible, and the air can no longer expand against the atmospheric pressure. Half the heat has gone in external work, and half remains in the expanded air, and must be thrown away if the air is to be brought back to its original state with the help of atmospheric pressure alone.

The conception of the Carnot cycle, with its extraordinary peculiarities, was quite evidently based, not on the study of actual heat-engines, but on Carnot's ideas, derived from the caloric theory, of how a heat-engine works. These ideas led him to the conclusion that in the working of a heat-engine, any change of temperature in the working substance, unless the change is accompanied by change in volume, is a waste of heat. Hence the strange feature of the Carnot cycle that in it there is no change of temperature without change of volume.

As we have already seen, the whole of the expansion and none of the compression must be adiabatic

¹ Abstract of a paper on "The Maximum Efficiency of Heat-Engines and the Future of Coal and Steam as Motive Agents," read before the Institution of Mining Engineers on June 16 by Dr J. S. Haldane, F.R.S.

in a heat-engine working with maximum efficiency. There must also be one and only one stage in which abrupt change of temperature occurs without change of volume. In the steam-engine with maximum expansion of the steam, there is abrupt rise of temperature at the beginning of the cycle. If, as in the Watt-Newcomen engine, there is also abrupt fall of temperature before expansion is complete, loss of efficiency is a necessary result.

At the present time steam-engines and oil-engines are running a neck-to-neck race as regards many employments, while elsewhere the oil-engine is everywhere being applied for quite new purposes, where no heat-engine had previously been applied. In the opinion of many persons the steam-engine is bound to be displaced more and more by the internal-combustion engine. This opinion is largely based on the current academic doctrine that the efficiency of a heat-engine depends on the absolute temperature reached in the engine. In the present paper the academic teaching has been thrown to the winds, backed though it be by the names of men to whom the whole world has good reason to be grateful. A step further may also now be taken. We suggest that the development of the steam-engine has been very greatly hindered by the fallacious teaching associated with Carnot's cycle. Engineers have been prevented from seeing clearly what the maximum efficiency of a heat-engine is, where that efficiency is being needlessly lost, and how the steam-engine can be modified to suit varying circumstances without loss, or with minimum loss, in efficiency.

We still use furnaces and boilers which waste much heat whenever an engine is temporarily out of action or doing only light duty, even though they may be so designed as to cause very little waste, during continuous full duty of the engine. It seems probable that the furnaces and boilers of the future will be gas fed, the gas being formed in a heat-insulated producer or carburettor, and only made and burnt as the steam

is required, the whole regulation being mechanical and the heat of the waste gases being nearly all returned to the furnace and boiler. Another alternative presenting similar advantages is the use of pulverised fuel. The boiler and furnace can then be made much smaller than is now usually the case.

As regards modifications of the steam-engine to suit varying circumstances, it seems that small engines, working at very high pressures, and with correspondingly small tubular boilers, will come more and more into use. A steam pressure of 100 atmospheres, with a corresponding temperature of 600° F., seems well within reach. At such a pressure the percentage loss of efficiency, owing to either the discarding of a condenser or condensation at or even somewhat above boiling-point, would not be too large. The bulky apparatus required for complete expansion can thus be dispensed with, reducing the engine to extremely compact proportions and very small weight. By these means the steam-engine can be rendered far more compact and adaptable to varying conditions under which only internal-combustion engines, or steam-engines without a condenser, are now used.

Perhaps too sanguine a view is taken of the future of the steam-engine, but it seems that in every case where either fuel economy or size of engine is of predominating importance, the steam-engine and coal will in the future displace the internal-combustion engine and oil. Even where oil or gas is alone desirable or available as fuel, it will probably turn out to be cheaper, where fuel economy and weight of engine are important, to use them as fuels for steam-engines. The latter will probably take the place of internal-combustion engines in even motor vehicles and aeroplanes. With the further development of electrical transmission of power obtained from coal and steam, the steam-engine and coal will also come more and more to the fore.

The Motion of Whales during Swimming.

By Dr. C. G. JOH PETERSEN, Director of the Danish Biological Station, Copenhagen

IN our two well-known Danish zoological handbooks it is stated regarding the swimming of whales, in one that "It is the screwing actions of the hind part of the body (the tail) which force the whale through the water, the tail fin acting only to balance up and down," in the other that "The whales move in the manner of fish by flapping the tail from side to side", according to a verbal statement, this was observed by the author himself on porpoises in a tank in the Zoological Garden. In the foreign literature I have found information¹ that whales, when swimming rapidly, move the tail fin up and down; when they swim slowly, on the other hand, they perform screw-like motions. Porpoises have been observed in tanks in England to swim by moving the tail fin up and down with slight undulations to each side.

Thus there seem to be greatly divergent opinions as to the manner in which whales effect their swimming movements. I have myself seen dolphins following, *e.g.*, the steamship of the Biological Station, and I have spoken with many others who have seen the same; we are agreed that it is impossible to see how they swim; they only tremble, but follow, apparently with ease, the largest steamship going at full speed.

In the spring of 1924 I was by chance present at a catch of porpoises in the Bramsnæs Vig (by Holbæk),

and there I bought the tail of a porpoise just caught. Dr Blegvad, the assistant of the station, and I dissected it, Fig. 1 is a sketch of the result. At the base the tail fin is very flexible, so long as it is in a fresh condition, similar to the carpus of the hand of man. The vertebræ here are very flexible in relation to each other, and the vertebral column extends right out to the posterior edge of the fin. No muscles are found in the tail fin itself, only four strong tendons extending right out to the extreme vertebræ. These tendons may move the horizontal fin up and down, but scarcely with any force, and doubtfully sideways. The flukes of the tail fin consist only of epidermis and fibrous tissue, they are somewhat elastic for movements up and down. Of other muscles in the tail (hind part of the body), there are two for lateral motions and two for vertical motions; they terminate with strong tendons some distance from the root of the tail fin.

The tail fin with its vertebræ may thus be moved up and down by bending at the root, but these movements do not seem to produce force enough for powerful swimming, because, amongst other reasons, the flukes will impede the speed considerably when in their extreme positions. One can well imagine that quick movements of the flukes towards the horizontal position may give a small speed, as when a rudder is moved in a little boat; this produces a slight speed, if the motions towards the central

¹ Beddard, "A Book of Whales," London, 1900, Murie, "On the Anatomy of a Fin-Whale," Proc. Zool. Soc., 1865; T. Bell Pettigrew, "Animal Locomotion," London, third edition, 1883

position are the strongest. But if we imagine that the extreme part of the tail (the hind part of the body) itself is moved up and down, even if these movements are only slight, the elastic fin would be enabled to take up suitable inclined positions for up-and-down movements and thus give effective power during the full extent of the motion (Fig. 2).

FIG. 1.—Combination of a vertical, transverse section and a vertical, longitudinal section through the tail of the porpoise. I, Dorsal muscle; 2, the two upper tail fin muscles; 3, the two lateral muscles; 4, the two lower tail fin muscles; 5, ventral muscle; 6, layer of blubber; 7, left upper and lower tail fin tendon. II, The tail fin seen from above, with its two upper tendons and the vertebrae denuded. III, Transverse section through the tail.

In order to try this, I had a thin steel plate made, shaped like the tail fin of a porpoise, and attached it to a vertical stick; when this stick was moved up and down in the water at a suitable speed (rhythm) the plate produced a powerful current rearward, simultaneously forcing the stick forward, against the edge by which I supported it. The steel plate I employed was too thin and flexible for a continuation of these experiments; for I could only "swim slowly" with it, and to procure a stronger one took so long, that I was not able to proceed further; but the experiment had proved, without doubt, that by means of small movements up and down of the terminal part of the tail, the tail fin of the dolphin may be employed as an excellent means of propulsion, inasmuch as its muscles (tendons) may give it the correct rigidity, corresponding with the varying speed through the water; in this the operations of the four named muscles and tendons surely may be sought. When the dolphin starts swimming, large movements are required to move a sufficiently large quantity of water, but, when speed is once gained, the water will be felt hard, and then only small but quick motions up and down, with more force and more rigidity in the tail for each stroke, are required. Dolphins are said to be able to follow destroyers up to a rate of about 30 knots, *i.e.* at the same speed as fast trains go between Copenhagen and Korsør.

It is the great drawback in all steamship propellers that their mould cannot conform with the variation in speed, and that they are quite without elasticity; they yield, therefore, only a comparatively small effective power. Mr. Vogt, an engineer, has endeavoured with the pendulum propeller to produce a variable pitch by means of a complicated system of springs (metal springs), and he really succeeded in this; but the construction seems to have been too expensive to make use of practically.

By means of the elastic and flexible structures of which the tail fin and the tail of the porpoise are made it is, on the other hand, possible to obtain an enormous effective power by comparatively few and

small movements; thus there is no need for astonishment that this little fin is really able to give such a high speed to the big animal. Mr. Vogt, with whom I have debated this matter, agreed fully with me on this point, as well as, on the whole, with my views upon this matter.

The objection may be raised to this illustration of the swimming movements of the whale, that the movements up and down of the tail itself must evidently impede the speed through the water; but the tail of the whale is, as a rule, so compressed in the terminal part that the resistance offered is considerably diminished, and, furthermore, it refers only to small, vertical movements.

As is well known, many fishes swim by performing lateral movements with the tail, because the fin is set vertically, *i.e.* on the same principle as the motions of whales, which only move the fin up and down, because this is situated horizontally; that fish in addition to these movements may also perform screw-like motions, is also well known from seeing goldfishes in aquaria. But they do this only when swimming slowly; if speed is desired, it is gained by means of strokes from side to side, analogous to the up-and-down strokes of the whales.

It is now easily understood why many people, including myself, who have observed dolphins following steamships during speed, have seen nothing but a trembling of their bodies, because the movements of the tail and the fin are up and down and comparatively slight, and vertical movements are not easily observed from above. Had there been sideways or screw-like motions, they could not have escaped the observer; that such movements also may be performed by whales, I do not doubt, but they occur only during quite slow movement, when the whale feeds, or when for some other reason it is in no hurry.

When, especially from observations of porpoises in tanks, lateral motions of the tail are mentioned, or

FIG. 2.—The positions of the tail fin (IV) during downward movement of the tail, (V) during upward movement of the tail.

that the tail is used in a fish-like manner by strokes from side to side, this evidently arises from the fact that here the animal the whole time had to steer in order to avoid running against the sides of the tank. The observations themselves undoubtedly are correct. But statements to the effect that the tail fin is exclusively used for steering up or down are false; it may be used for this, and certainly also for steering sideways, but the flukes of the tail fin are the proper

organs for propulsion of the whale, as the propellers are in a ship, and the importance of the tail (hind part of the body) corresponds to that of the ship's engine which moves the propeller.

If we compare the size of the propeller of a steamship with the size of the ship, the propeller seems small, and still it may, in spite of its slight effective power, propel the ship, the tail fin of a dolphin or a whale is not smaller in comparison with the size of these animals than the propeller of the steamship, but larger, if anything. Thus, bearing in mind the obviously far greater effective power of the fins of

the whales, it is not to be wondered at that these animals may follow the biggest steamships with ease, and even follow our quick destroyers; in fact, a harpooned whale may carry away a steamship with great velocity through the water, in spite of the steamer backing full speed with its propeller.

I have presumed that the anatomy of the tail and the tail fin is mainly the same in the porpoise as in the other whales, this, however, as well as so many other things concerning this matter, I must leave to others, who may get an opportunity to examine it more closely.

Physics in Radiology.

SEVERAL notable papers were read before the Physics Section of the International Congress of Radiology, which was held at the Central Hall, Westminster, on June 30-July 4. The work of the Congress began with a joint discussion, in which the Physics and Radiology Sections met for a full day's consideration of the difficult problem of X-ray measurement. This discussion was opened at 10 A.M. on July 1 before a large attendance, by Sir William Bragg and Dr. Becquerel, the president (Dr. T. Holland) occupying the chair. The importance of such a discussion, in which representative men from practically all over the world took part, is obvious, and it is satisfactory to be able to report that the practical outcome has been a definite proposal as to the mode of initiating the formation of an International Committee to deal with the matter.

Sir William Bragg dealt generally with the importance of physical measurements and referred to the difficulties already met with in determining the brightness of light. He pointed out that the X-ray problem has special added difficulties of its own. First comes the question of a unit, and then the production of standards to be expressed in terms of the agreed unit, and finally it remains to ascertain what biological effects are associated with certain rays, or groups of rays, so measured. He was hopeful that a successful issue will ultimately result from the efforts now being made throughout the world towards setting up a suitable system of X-ray measurement, but he warned his hearers that the question of an X-ray unit is beset with more difficulties than have ever been met with in the case of any other unit which science has been called upon to devise. Finally, he directed attention to the principles which must underlie such a system, and set the problem clearly before the meeting.

Dr. Becquerel, of Paris, spoke more in detail with reference to the conditions which the medical radiologist has to face, referring to the pioneer work of Villard, and discussing the actual methods of measurement suggested by Solomon, Kronig and Friederich, Seit and Wintz, and others. He made an eloquent appeal for international unity in regard to the question of X-ray measurement.

On the conclusion of the formal opening of the discussion, the chairman of the Physics Section (Major C. E. S. Phillips) presided for the rest of the day. In the course of his remarks, Dr. Becquerel strongly urged the setting up of an International Committee to deal with X-ray measurements, and Dr. Finzi, who spoke later, also directed attention to the matter and seconded Dr. Becquerel's proposal, which on being put to the meeting was carried with enthusiasm.

Dr. Becquerel was followed by Dr. Solomon (France), Dr. Behnken (Germany), Prof. Grebe (Germany), Dr. Altschul (Czechoslovakia), Dr. Shaxby (Cardiff), who read a communication from Dr. A. Dauvillier

(France), Dr. Finzi (London), Dr. Moore (London), Prof. Wintz (Germany); Dr. Reyjeski (on behalf of Prof. Dessauer), Dr. Glasser (U.S.A.), Prof. Friederich (Germany), Dr. Mallet (France), Dr. Holdfelder (Germany), Prof. Holthausen, Dr. Coliez, Prof. Crowther (Reading), Prof. Russ (London), and Dr. Ernst (U.S.A.). The chairman directed attention, at the conclusion of the discussion, to the principal points raised, and emphasised the desirability of taking steps towards the establishment of an International Committee to pursue the subject.

On Wednesday evening the Silvanus Thompson Memorial Lecture (inaugurated by the Röntgen Society) was delivered (in English) by the Duc de Broglie, and attracted an enthusiastic audience. The nature of the secondary radiations set up by X- and gamma rays, and attempts to understand the process by which they are initiated, are matters of great importance and interest to radiologists generally, and especially to those searching for clues as to a biophysical explanation of the effects of radiations upon tissues. The Duc de Broglie eloquently summarised our present knowledge of this subject, and gave a valuable account of some recent researches by French physicists who have been extending the work begun by Rutherford, C. T. R. Wilson, Ellis, and others, relating to the problem. At the conclusion of the lecture the Silvanus Thompson Memorial Medal was handed to the Duc de Broglie by the president.

On Thursday morning an interesting paper on the radiography of coal was read by Mr. Norman Kemp, and Dr. Bouers then described a new metal X-ray tube (Metalix) for use in radiography and X-ray therapy. This was followed by an important paper by Prof. Friederich (Freiburg) in which some new results were described. The last paper of the morning was read by Dr. Koopman, of Amsterdam, who showed a novel type of Potter-Bucky diaphragm. The variety and originality of these papers were striking, and interesting discussions followed each one of them.

In the afternoon the Section did not meet, on account of the visit to the National Physical Laboratory, which had been arranged for that day in response to the kind invitation of the Director.

The Section again met on Friday morning at 10 A.M. for a discussion of methods of protection, opened by Dr. G. W. C. Kaye, of the National Physical Laboratory. An animated debate followed, to which M. Pilon (Paris) sent a written contribution (read by Mr. Gough), and the following took part: Dr. Ferreux (Paris), Mr. Pullin (London), Dr. Pirie (Montreal), Dr. Shaxby (Cardiff), and Dr. Moore (London). Dr. Kaye, in his reply, directed attention to the need of standardising the scheme of protection, and proposed the following resolution, which was seconded by Mr. Pullin and unanimously agreed to:

"That the Physics Section of the first International

Congress of Radiology wishes to place on record the desirability of adopting a standard scheme of X-ray and radium protection throughout the world."

The morning session was brought to a close with a valuable paper by Prof. F. L. Hopwood, who dealt in detail with the organisation of a hospital radium service. Considerable discussion ensued, in which Dr. Ferreux, of the Radium Institute, Paris, and Dr. Failla, of the Memorial Hospital, New York, took part.

The afternoon session was opened with a paper (read in title only) by Dr. George Clark (U.S.A.), which was followed by an interesting contribution by Dr. Lewis Simons (London), entitled "The Basis of the Selective Chemical Action of X-rays and Light," and the work of the Section was brought to a close by a discussion dealing with modes of producing currents at constant high potential. This discussion was opened by the chairman (Maj. C. E. S. Phillips), who gave a general survey of the subject. Many speakers stated their views, and Prof. Dessauer described his new methods now in use in Germany. Dr. Moore, Mr. Gunstone, and others contributed to the discussion in which all were agreed as to the desirability of adopting constant high-tension apparatus for accurate physical or therapeutic work.

It is clear from the work of the Congress that physics is playing an important part in the progress of medical radiology, and that the scope of its use-

fulness is ever widening. The study of X-ray spectroscopy, for example (to mention only one aspect of it), has already led to the design of wave-length measuring instruments for use in the ordinary routine work of a medical X-ray department, as well as furnishing a knowledge of organic structures unobtainable by other means. A well-organised exhibition of apparatus held in conjunction with the Congress also testified to the many practical applications that have arisen from work in radiation physics, which has been carried out in many parts of the world during recent years, as well as to the ingenuity of those who provide appliances for medical radiologists.

The truly international character of the Congress was very striking. There were representatives from India and Iceland, from Sweden, Russia, Czechoslovakia, France, Belgium, Germany, Italy, U.S.A., Canada, and so forth; and it was a remarkable fact that this great medical meeting had been made possible by the researches of a physicist whose rare distinction it was to have given to the world a discovery of such far-reaching possibilities for the good of mankind. It was generally acknowledged that the Congress had proved a success; it had, in fact, brought together representative men from many parts of the world, whose enthusiasm was tempered only by a desire to advance cautiously in a field of medical work which is admittedly still imperfectly understood.

C. E. S. PHILLIPS.

Industrial Water Supply.

THE subject of industrial water supply and stream pollution was discussed at the joint meeting of the Institution of Chemical Engineers and the American Institute of Chemical Engineers, which was held on July 17, in Leeds. Messrs. F. P. Veitch and L. C. Benedict, of the Bureau of Chemistry (U.S.A.), contributed a valuable paper on the composition and disposal of wool-scouring waste liquors, in which they described current methods of recovering wool-grease and fertilising material from them, as well as recent work done by the Bureau which indicates the superior advantages of extracting with naphtha and subsequent scouring with soap and water. They estimate that the wool-scouring liquors annually produced in the United States contain, in millions of pounds weight, grease 60-70, potash salts 40-48, nitrogenous matter 15, and dirt 60-90, the total value of which is about 5 million dollars. The authors are convinced that wholesale economic recovery of the valuable ingredients is possible.

Mr. W. L. Stevenson, chief engineer to the Department of Health, Commonwealth of Pennsylvania, criticised most legislative efforts to control pollution of streams as being too peremptory and too punitive, and he advocated the policy of scientific and friendly co-operation between municipality and manufacturer; such a policy is successfully pursued by the Sanitary Water Board of Pennsylvania, which, *inter alia*, has re-classified the waters of that State on the principles of conservation and controlled utilisation. The nature of the restrictive and penalising legislation passed by most States was well shown by Mr. E. B. Bessehevre, of New York, whose paper included a summary of the rules upon which the decisions of courts of justice have been based. Mr. H. C. Parker, of Pennsylvania, described recent developments and improvements in the apparatus used for determining hydrogen-ion concentration in industrial effluents and sewage liquors.

Of the papers presented by British workers, that by Dr. T. Lewis Bailey, of the Ministry of Health, on effluents from ammonia plants of coke-oven and

gas-works, was of outstanding importance. Such effluents, it is well known, are the source of much trouble at sewage-disposal works, and Dr. Bailey has for years past been investigating methods of prevention and cure. He described the probable origins of, and the possible ways of eliminating, the harmful ingredients (chiefly ammonium thiocyanate, ammonium thiosulphate, phenol, organic bases and higher tar-acids), but holding that prevention is better than cure, he indicated how relatively clean ammoniacal liquors can be produced by minimising the time of contact between tar and liquor, and by rapidly cooling the crude gas in water-cooled systems, together with rigid exclusion of "adventitious" air. Bad effluents from ammonia plants can be successfully purified in percolating filters, given proper dilution and adequate regulation, although this method is seldom practicable at gas-works owing to lack of the necessary ground space.

Mr. R. D. Littlefield, also of the Ministry of Health, retold the interesting tale of how the Royal Commission on Sewage Disposal solved the problem of purifying the effluents from Scottish distilleries. Here again the percolating filter did what was required, after suitable inoculation.

Water-softening by the base-exchange method was the subject of two contributions. Dr. E. B. Higgins and Mr. J. P. O'Callaghan summarised the advantages which this method has over the older lime-soda process, and described in outline the preparation of "Permutit," both the artificial material (made from sodium silicate and sodium aluminate) and the natural material, which is prepared from greensand or glauconite. In their opinion, natural zeolite is the better owing to its rapidity of action and of regeneration with sodium chloride solution, as well as on account of its superior mechanical and chemical stability. On the other hand, Dr. T. P. Hilditch and Mr. H. J. Wheaton claimed that the water-softener "Doulcil" is practically free from the defects which the previous authors held to be inherent in all such artificial base-exchange materials.

Societies and Academies.

EDINBURGH.

Royal Society, July 6.—G. Leslie Purser: *Calamoichthys calabaricus* Smith. Pt. i. The alimentary and respiratory systems. *Calamoichthys* is the less known of the two genera of the Polypterini. The histology of the alimentary tract is not so complex as the anatomy would lead one to expect, as the intestinal epithelium is practically the same throughout its length; and as a whole the digestive tract is of a simple piscine type. Gills are well developed, but in addition there is, opening into the pharynx by a median ventral glottis, a pair of lungs, the minute structure and the vascular connexions of which show how well the pulmonary respiratory mechanism is developed.—W. W. Taylor: The precipitation of sols by polyvalent ions. With the alkali salts of methanesulphonic acid and naphthalenetrisulphonic acid, which are neutral, there is only one zone of precipitation of ferric hydroxide sol, which commences abruptly at about 0.0002 *N* and extends up to the saturated solution. It is not followed by a zone of no-precipitation. The range investigated was from 7×10^{-8} *N* to nearly 1.5 *N*. They thus fall in line with the neutral chloride and sulphate solutions. The two zones of precipitation, separated by a zone of no-precipitation ("reversal") obtained with sodium phosphate, which contains OH' and no trivalent anion, is ascribed to the OH'. If this be the case, the analogous behaviour of negative sols with ferric and aluminum salts will be due to their hydrolysis. Whether the presence of a polyvalent ion is also necessary is not certain. With the neutral anions, more or less periodic variations in the rate of precipitation were observed; these are not due to errors in procedure. The valency rule does not hold in the case of the above trivalent anions.—E. Neaverson: Ammonites from the Upper Kimmeridge Clay. The Upper Kimmeridge Clay includes a variable series of clays and sands lying between the Gravesia zones of the Lower Kimmeridgian and the base of the Portland Stone Series. The zonal sequence is here tabulated with equivalent stratigraphical terms.

- | | |
|-----------------------|---|
| 5. pallasioides zone | } Hartwell Clay |
| 4. rotundum zone | |
| 3. pectinatus zone | Swindon Sands; Oil Shale of Kimmeridge. |
| 2. nodiferous zone | } Kimmeridge Clay (in part) |
| 1. Wheatleyensis zone | |

The ammonites have hitherto been grouped under the name *Ammonites biplex* which, as Lamplugh pointed out thirty years ago, is useless for stratigraphical purposes. Though the forms found in the Hartwell Clay are familiar (but undescribed), those in the lower two zones are practically unknown in literature, and none has previously been described or figured. Some of these ammonites have been recognised in the Upper Kimmeridge Clay (*sensu anglico*) of Boulogne, but their identity with Russian forms (suggested by Pavlov and others) is not accepted. Indeed, palæogeographical considerations seem to indicate that the British and Russian areas were not in direct communication during the period when these ammonites flourished.—Prof. A. A. Lawson: A contribution to the life-history of *Bowenia*.—J. E. Nichols: Meteorological factors affecting fertility in sheep. The association of climatic conditions at times of service and lambing in a Cheviot and a Blackface flock, kept under the same conditions of pasturage, altitude and management for fourteen years, and data of fertility are examined. Significant evidence of differential responses of the two breeds are presented, and of the meteorological factors considered, the mean tempera-

ture at time of service is shown to exert the greatest influence.

PARIS.

Academy of Sciences, July 15.—G. Bigourdan: The mean errors of the various modes of observation of the time signals. Over their longest paths, the perturbations of Hertzian waves have no influence on the time of transmission exceeding 0.01 sec. The error due to the mode of reception of the waves is of the same order of magnitude.—René Lagrange: The uniform deformation of a beam and the equation $\frac{\partial^4 F}{\partial x^4} + 2 \frac{\partial^4 F}{\partial x^2 \partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0$.—Eydoux: The graphical determination of the meridian lines of turbine blades.—P. Choux: The Cupanæ of Madagascar.—A. Tronchet: Vascular acceleration in schizocotyly.—Alexandre Lipschutz: Unilateral phenomena resulting from castration.—Henri Pottevin and Robert Faillie: Work during walking.

CAPE TOWN.

Royal Society of South Africa, June 17.—A. W. Roberts: A statistical inquiry into the population problem in South Africa. The rate of increase of the white population in the Cape Colony is subject to a cyclical variation completed in 170 years. The rate of increase has been decreasing during the past twenty years. In Natal, exact statistics go back to 1860, and again there is evidence of cyclical variation. The rate of increase has been steadily decreasing during the past ten or fifteen years. This condition is also found in the Orange Free State and the Transvaal. Early enumerations of the native population are not available. Those taken in recent years indicate a declining rate in every instance but one, Zululand. The rate is increasing here, but very slowly.—W. J. Copenhagen: A note on Azotobacter in some South African soils. Soils from a number of localities in the Cape Province were examined and records made of the hydrogen-ion concentration, moisture, amount of organic matter, nitrogen per gram, characters of cultures, and nitrogen fixed per culture.—J. Moir: Colour and chemical constitution, Pt. xx.: Some residual problems.

ROME.

Royal Academy of the Lincei, June 5.—P. Burgatti: Conditions of validity of Lagrange's equations.—U. Cisotti: Fundamental equations of potential laminary motions on any surface.—G. Armellini: A theorem on the problem of two bodies of increasing masses.—N. Parravano and G. Malquori: Reactivity of silver with oxygen.—C. F. Parona: New observations on the chalks with *Heterodicerus Luci* of the Parenzo coast in Istria.—Gaetano Rovereto: New observations on the crystalline mass of Savona.—E. Carano: Detailed development of the female gametophyte of *Euphorbia dulcis* L.—Fil. Bottazzi and L. De Caro: Further results on the variations in the electrical resistance of muscles caused by solutions having different P_n values.—A. L. Herrera: Imitation of the smallest details of the Microsporidia by means of calcium fluosilicate.—Gianna Calzolari: Totality of analytical functions.—Minea Chini: Determination of the geodetics of certain surfaces.—Gaetano Scorza: Complex algebraics connected with groups of infinite order.—Vasco Ronchi: A new stellar interferometer.—A. Ferrari: Crystalline lattices and isomorphism of lithium and magnesium fluorides. The structure of magnesium fluoride is of the rutile type, and the volumes of the elementary cells, containing four

molecules in the case of lithium fluoride and two in that of magnesium fluoride, are practically equal.—G. Cannieri and L. Fernandes: Contribution to the study of certain minerals containing thallium: thermal analysis of the systems, $Tl_2S-As_2S_3$ and Tl_2S-PbS .—G. Scagliarini: Complexes of quinquevalent molybdenum.—Ardito Desio: The geological constitution of some of the smaller islands of the Dodecanese.—C. Jucci: Races of silkworms with three or four mutations: Study of crosses.

Supplement to NATURE

No. 2913

AUGUST 29, 1925

The Figure and Constitution of the Earth.¹

By Prof. HORACE LAMB, Sc.D., LL.D., F.R.S., President of the British Association.

WHEN one is confronted, as on this occasion, with the British Association in plenary session, it is permissible, I hope, to indulge in a few reflections on the nature and purpose of science in general. The theme is no new one and has never been discussed so frequently as in our time, but the very range of our activities entitles us to consider it from our own point of view. The subjects treated at these meetings range, according to the titles of our Sections, from the most abstract points of mathematical philosophy to the processes of agriculture. Between these limits we have the newest speculations of astronomy and physics, the whole field of the biological sciences, the problems of engineering, not to speak of other matters equally diverse. These subjects, again, have become so subdivided and specialised that workers in adjacent fields have often a difficulty in appreciating each other's ideas, or even understanding each other's language. What then is the real purpose of science in the comprehensive sense; what is the common inspiration, the common ambition, behind such enthusiastic and sustained effort in so many directions?

The question may seem idle, for a sort of official answer has often been given. It was deemed sufficient to point to the material gains, the enlarged powers, which have come to us through science, and have so transformed the external part of our lives. The general aim was summed up in an almost consecrated formula: "to subdue the forces of Nature to the service of man"; and since it was impossible to foresee what abstract research might or might not provide a clue to something useful, the more speculative branches of science were not only to be tolerated, but also to be encouraged within limits, as ancillary to the supreme end. And, it must be said, the cultivators of these more abstruse sciences have themselves been willing sometimes to accept this position. The apologists of pure mathematics, for example, have been wont to appeal to the case of the conic sections, which from the time of Apollonius onwards had been an entirely detached study, but was destined after some 2000 years to guide Kepler and Newton in formulating the laws of the

planetary motions, and so ultimately to find its justification in the Nautical Almanac.

I will not stop to examine this illustration, which I personally think rather strained. We may recognise that practical utility has been a conscious though not the sole aim in much scientific work, and sometimes perhaps its main justification; but we can scarcely admit that any such formula as I have quoted worthily conveys what has been the real inspiration of discovery through the ages. If we may go back to Apollonius and the conic sections, we cannot suppose that he was thinking of posterity at all; he was engaged in a study which he no doubt held to be legitimate and respectable in itself. Or, to take a very recent instance, when Faraday and Maxwell were feeling their way towards an electric theory of light, they could scarcely have dreamed of wireless telegraphy, though, as we now know, this was no remote development. The primary aim of science as we understand it is to explore the facts of Nature, to ascertain their mutual relations, and to arrange them so far as possible into a consistent and intelligible scheme. It is this endeavour which is the true inspiration of scientific work, as success in it is the appropriate reward. The material effects come later, if at all, and often by a very indirect path.

We may, I think, claim for this constructive task something of an æsthetic character. The provinces of art and science are often held to be alien and even antagonistic, but in the higher processes of scientific thought it is often possible to trace an affinity. The mathematician, at all events, is at no loss for illustrations of this artistic faculty. A well-ordered piece of algebraical analysis has sometimes been compared to a musical composition. This may seem fantastic to those whose only impression is that of a mass of curious symbols; but these bear no more resemblance to the ideas which lie behind them than the equally weird notation of a symphony bears to the sounds which it connotes or the emotions which these evoke. It is no misplaced analogy which has led enthusiasts to speak of the poetical charm of Lagrange's work, of the massive architecture of Gauss's memoirs, of the classic perfection of Maxwell's expositions. The devotees of other

¹ Inaugural address delivered to the British Association at Southampton on August 26.

sciences will be at no loss for similar illustrations. Is it not the case, for example, that the widespread interest excited by the latest achievements of physical science is due not to the hope of future profit, though this will doubtless come, but to the intrinsic beauty as well as the novelty of the visions which they unfold?

It is possible, I trust, to insist on these aspects of the scientific temperament without wishing to draw a sharp and even mischievous antithesis between pure and applied science. Not to speak of the enormous importance in our present civilisation of the material advantages which have come in the train of discovery, it would be disloyal to science itself to affect to depreciate them. For the most severely utilitarian result comes often as the result of a long and patient process of study and experiment, conducted on strictly scientific methods. We must recognise also the debts which pure science in its turn owes to industry, the impulse derived from the suggestion of new problems, and not least the extended scale on which experiment becomes possible. Reference may appropriately be made here to the National Physical Laboratory, initiated mainly in the higher interests of industry, which by the mere pressure of the matters submitted to it is becoming a great institute of theoretical as well as applied science, informed throughout by the true spirit of research.

But perhaps the most momentous consequences of the increased scientific activities of our time have been on the intellectual side. How profound these have been in one direction we have recently been reminded by the centenary of Huxley. Authority and science were at one time in conflict over matters entirely within the province of the latter. The weapons were keen and the strife bitter. We may rejoice that these antagonisms are now almost obsolete; one side has become more tolerant, the other less aggressive, and there is a disposition on both sides to respect each other's territories. The change is even reflected in the sermons delivered before the British Association. The quarters where we may look for suspicion and dislike are now different; they are political rather than ecclesiastical. The habit of sober and accurate analysis which scientific pursuits tend to promote is not always favourable to social and economic theories, which rest mainly on an emotional if very natural basis. Some of us, for example, may remember Huxley's merciless dissection of the theory of the social contract. There is hence to be traced, I think, a certain dumb hostility which, without venturing on open attack, looks coldly on scientific work except so far as it is directed to purposes of obvious and immediate practical utility.

There is a more open kind of criticism to which we are exposed, which we cannot altogether ignore, though it again rests on a misconception of the true function of

science. It is to be met with in quarters where we might fairly look for countenance and sympathy, and is expressed sometimes with great force, and even eloquence. The burden is one of disappointment and disillusion; we even hear of the "bankruptcy of science." It seems to be suggested that science has at one time or other held out promises which it has been impotent to fulfil; that vague but alluring hopes which it has inspired have proved delusive. It may be admitted that extravagant and impossible claims have sometimes been made on behalf of science, but never, I think, by the real leaders, who have always been most modest in their claims and guarded in their forecasts. It is true, again, that in the enthusiasm which attended the first sensational developments of modern industry, hopes were conceived of a new era where prosperity would ever increase, poverty would be at least mitigated and refined, national antipathies would be reconciled. When these dreams did not swiftly come true there was the inevitable reaction; the idols were cast down, and science in general has rather unreasonably come in for its share of depreciation. The attitude which I have been trying to describe is put very forcibly in a quotation from President Wilson which I saw not long ago, though its date is not very recent:

"Science has bred in us a spirit of experiment and a contempt for the past. It made us credulous of quick improvement, hopeful of discovering panaceas, confident of success in every new thing. . . . I should fear nothing better than utter destruction from a revolution conceived and led in the scientific spirit. Science has not changed the laws of social growth or betterment. Science has not changed the nature of society, has not made history a whit easier to understand, human nature a whit easier to reform. It has won for us a great liberty in the physical world, a liberty from superstitious fear and from disease, a freedom to use nature as a familiar servant; but it has not freed us from ourselves."

The tone is one of bitter disillusion, but we may ask why should science, as we understand it, be held responsible for the failure of hopes which it can never have authorised? Its province, as I have tried to define it, is vast, but has its limits. It can have no pretensions to improve human nature; it may alter the environment, multiply the resources, widen the intellectual prospect, but it cannot fairly be asked to bear the responsibility for the use which is made of these gifts. That must be determined by other and, let us admit it, higher considerations. Medical science, for example, has given us longer and healthier lives; it is not responsible for the use which we make of those lives. It may give increased vitality to the wicked as

well as the just, but we would not, on that account, close our hospitals or condemn our doctors.

In spite of the criticisms I have referred to, we may still hold up our heads, let us hope without arrogance, but with the confidence that our efforts have their place, not a mean one, in human activities, and that they tend, if often in unimagined ways, to increase the intellectual and the material and even the æsthetic possessions of the world. In that assurance, we may rejoice that science has never been so widely and so enthusiastically cultivated as at the present time, with so complete sincerity, or (we may claim) with more brilliant success, or even with less of international jealousy.

Passing from these reflections, which are, I hope, not altogether inopportune, it is expected that the president of the British Association should deal with some subject in which he has himself been interested. For a mathematician this obligation is a specially difficult one, if he is not to overstrain the patience of his audience. I propose to speak briefly, and mainly from the mathematical and physical point of view, about some branches of geophysics, and in particular those relating to the constitution of the earth. It is a subject which in the past has often engaged the attention of the Association. I need only recall the names of Kelvin and George Darwin, and the controversies with which they are associated. Historically, it is of special interest to the mathematician and the physicist, for it was in his researches on the figure of the earth that Laplace initiated the theory of its potential, with its characteristic equation, and so prepared the way for Poisson, Green, Cauchy, and a host of followers, who developed the theory of electricity and ultimately that of light. To go further back, it was in this connexion that Newton found an important verification of his law of gravity. Quite recently, the whole subject has been reviewed in a valuable treatise by Dr. Jeffreys, who arrives at conclusions which are at all events definite, and maintained with great ability.

I do not propose to deal with the fascinating speculations as to the past history of the earth and its reputed child, the moon, which will be more or less familiar. I must confine myself to a rapid survey of the information as to its present constitution, which can be gathered from observations made in our own time, and capable of repetition at will. This, though less exciting, is at all events a region in which imagination is more subject to control.

The accurate investigation of the figure of the earth is intimately connected with the variation of gravity over its surface. In view of the local irregularities, some convention was necessary as to what is meant by the shape of the earth as a whole. The usual

definition is that it is a level surface as regards the resultant of true gravity and centrifugal force: often that particular level surface of which the sea forms a part. I need not dwell on the immense amount of theoretical and practical labour which has been devoted in various countries to the determination of the geometrical surface which most nearly satisfies this requirement. Of more recent interest are the irregularities in the intensity of gravity, which have been found to exist over wide areas, by the highly trained Survey of India, by the Coast and Geodetic Survey of the United States, and by various observers on the continent of Europe. Briefly, the general result is this, that in mountainous regions the observed value of gravity is abnormally low, whilst on oceanic islands, and so far as can be ascertained on the sea, it is abnormally large, when all allowance has been made for altitude and the normal variation with latitude. The fact that this has been found to be the case in so many different places, shows that we have here to deal with no casual phenomenon.

The accepted explanation, originated by Archdeacon Pratt, of Calcutta, in 1859, and since developed by Hayford and Bowie, of the U.S. Survey, is that if we imagine a level surface to be drawn at a depth of about 100 kilometres, the stratum of matter above this, though varying in density from point to point, is approximately uniform, in the sense that equal areas of the surface in question bear equal weights. The altitude of the mountains is held to be compensated by the inferior density of the underlying matter, whilst the oceanic hollows are made up for by increased density beneath. Leaving aside the technical evidence on which this hypothesis is based, there are one or two points to be noticed. In the first place it suggests, as is highly plausible on other grounds, that the matter in the interior of the earth, below the stratum referred to, is in a state of purely hydrostatic stress, *i.e.* of pressure uniform in all directions. So far as this stratum is concerned, it might be floating on an internal globe of liquid, although no assertion is really made, or is necessary, to this effect. But in the stratum itself, shearing forces must be present, and it is necessary to consider whether the actual material is strong enough to withstand the weight of continents and mountains, and the lack of lateral support due to the oceanic depressions. The researches of Prof. Love and others show that this question can fairly be answered in the affirmative.

The accurate determination of the acceleration of gravity at any place is, of course, a matter of great delicacy. Not to mention other points, in the pendulum method the yielding of the support due to the reaction of the pendulum as it swings to and fro affects

the time of oscillation. It may be recalled that, so far back as 1818, Kater, in his absolute determination of the length of the seconds pendulum in London, was on his guard against this effect, and devised a test to make sure that it was in his case negligible. In a portable apparatus, such as is used for comparative determinations, it is difficult to give sufficient rigidity to the support, and a correction has, in some way, to be applied. Recently, Dr. F. A. V. Meinesz, of the Dutch Survey, who has carried out an extensive gravity survey in Holland, has sought to minimise this effect by the use of pairs of pendulums swinging in opposite phases, and so reacting on the support in opposite senses. This has opened out a prospect of accurate gravity determinations at sea. The use of a pendulum method on a surface vessel is scarcely possible, but a submarine when sufficiently immersed offers comparative tranquillity, and it is hoped that the small residual horizontal motions may be capable of elimination, and the diminished vertical oscillation allowed for. The methods previously employed at sea which could claim any accuracy are those of Hecker. In one method, the pressure of the atmosphere is found in absolute measure from the boiling point of water and compared with the gravitational measure afforded by the barometer. In a more recent method, also devised by Hecker, and followed with some modifications by Duffield, the idea is to carry about a standard atmosphere, *i.e.* a mass of air at constant volume and prescribed temperature, the pressure of which is measured gravitationally by the barometer. Both methods are highly ingenious, but cannot compete as regards accuracy with the pendulum method if this should be found practicable.

It is a matter of regret that the observational side of geophysics has of late been so little cultivated in Great Britain. In India, with its wide opportunities, geodetic and gravitational work has long been carried on with high efficiency, and has furnished essential material for the generalisations I have referred to. But in the Home country, although we have an admirable topographical survey, nothing so far as I know has been done towards a gravity survey since the time of Kater, more than a century ago. Proposals for the establishment of a formal Geodetic Institute, such as existed in some other countries before the War, which should embrace this as well as other subjects, have been urged, but have had to be abandoned owing to the exigencies of the time. It is therefore some satisfaction to record that a modest beginning has been made at Cambridge by the institution of a readership in geodesy, and that, when the requisite pendulum outfit is complete, it is hoped that a gravity survey of the British Isles may be initiated. The physical features are scarcely so rugged that sensational results such as were found in India are to be expected; but it is desirable that the work, which will involve comparatively little labour and expense after the initial steps, should be carried out. The example of Holland shows that in a country which has no outstanding features at all, a survey may reveal peculiarities which are at all events of considerable interest. I may add that it is contemplated that the Cambridge apparatus should also be designed to eliminate the disturbing element I have mentioned,

and that it should be available for determinations at sea. It is perhaps not too much to hope that, with the co-operation of the Navy, the gravity chart of the world, which is so far almost a blank as regards the ocean, may in this way be gradually filled in.

The distribution of the intensity of gravity over the surface of the earth gives by itself no positive information as to the distribution of density throughout the interior, though the contrary view has sometimes been held. For example, a spherical globe with a uniform intensity of gravitation over its surface would not necessarily be homogeneous, or even composed of spherical strata each of uniform density, however plausible this might be on other grounds. Consequently, there is room for hypothesis. There are certain tests which any hypothesis has to satisfy. It must account for the observed distribution of gravity, and having regard to the phenomena of precession, it must give the proper relation between the earth's moments of inertia about a polar and an equatorial axis. It may be added that it should be fairly consistent with the ascertained velocities of seismic waves at different depths, and the degree of elasticity which it is allowable to assign to the material. The somewhat artificial laws of density adopted by Laplace and Roche, respectively, mainly on grounds of mathematical convenience, have lost much of their credit. A more natural law, suggested indeed by Thomson and Tait in 1867 in their book on natural philosophy, has since been proposed in a more definite form by Wiechert. On this view, the earth is made up of a central core of about four-fifths the external radius, of high density, about that of iron, surrounded by an envelope of about the density of the surface rocks. This is, of course, only to be taken as a rough picture, but it satisfies the requirements I have mentioned, and is apparently not incompatible with the seismic data.

In all speculations on the present subject, considerations as to the thermal history of the earth and the present distribution of temperature in the interior play an essential part. The apparent inconsistency between the requirements of physics and geology was long a matter of controversy, and has given rise to keen debate at British Association meetings. Lord Kelvin's historic attempts to limit the age of the earth, by consideration of the observed temperature gradient as we go downwards from the surface, lost their basis when it was discovered that the rate of generation of heat in the processes of radioactive change was amply sufficient to account for the present gradient, and would even be far more than sufficient unless the amount of radioactive material concerned were strictly limited. Assuming an average distribution of such material similar to what is found near the surface, a stratum of some 16 kilometres in thickness would provide all that is wanted. Radioactive speculation has gone further. A comparison of the amounts of uranium, and of the end-products associated with it, has led to estimates of the time that has elapsed since the final consolidation of the earth's crust. The conclusion is, that it must lie definitely between 10^9 and 10^{10} years. The figure is necessarily vague owing to the rough value of some of the data, but even the lower of these limits is one which geologists and biologists are, I believe, willing to accept, as

giving ample scope for the drama of evolution. We may say that physics has at length amply atoned for the grudging allowance of time which it was once disposed to accord for the processes of geological and biological change.

The radioactive arguments on which these estimates are based are apparently irrefutable; but from the physical point of view there are reasons why one would welcome an extension even of the upper limit of 10^{10} years if this could possibly be stretched. For if this barrier be immovable, we are led to conclusions as to the present internal temperature of the earth which are not quite easy to reconcile with the evidence as to rigidity to be referred to in a moment. In the space of time I have mentioned, enormous as it is, the great mass of the earth could scarcely have cooled very much from the temperature when it was in a state of fusion. The central portion, whatever its nature, and however high its thermal conductivity, is enclosed by a thick envelope of feebly conducting material, just as a steam boiler, for example, may be jacketed with a layer of asbestos. To take a calculable hypothesis, we may assume with Wiechert that we have a central core of three-fourths the earth's radius, with an outer shell of rock. We may give the core any degree of conductivity we like; for mathematical simplicity we may even regard it as infinite. Then, if the outer layer consists of material having some such conductivity as the surface rocks, the internal temperature would take to fall to one-half its original value a period of at least ten times the limit I have named. It is obvious that the details of the assumption may be greatly varied without affecting the general conclusion of a very high internal temperature.

The question as to the degree of rigidity of the earth has so often been dealt with that a brief recapitulation must suffice. It was about the year 1862 that Kelvin first pointed out that if the earth as a whole were only as rigid as a globe of glass or even steel, it would yield so much to the deforming action of the solar and lunar tidal forces as seriously to affect the amplitudes of the oceanic tides, which are a differential effect. Unfortunately, the tides are so much complicated by the irregular distribution of land and sea that a comparison with the actual values of the theoretical amounts which they would have on the hypothesis of absolute rigidity is hopeless. The fortnightly tidal component, due to the changing declination of the moon, is probably an exception, but the difficulty here is to extract this relatively minute component from the observations, and the material is consequently imperfect. The problem was attacked in a different way by G. and H. Darwin in 1881. The horizontal component of the lunar and solar disturbing forces must deflect the apparent vertical, and it was sought to measure this effect by a pendulum. The quantities to be determined are so excessively minute, and the other disturbing forces so difficult to eliminate, that the method was only carried out successfully by Hecker in 1907, and afterwards by Orloff in Russia. The results on the whole were to the effect that the observed deflexions were about three-fifths of what they ought to be if the earth were perfectly unyielding, and were, so far, in accordance with estimates previously made by Darwin and others, from the somewhat imperfect statistics of the fortnightly tide.

There was, however, a discrepancy between the results

deduced from the deflexions in the meridian and at right angles to it, which gave rise to much perplexity. The question was finally set at rest by Michelson in 1916. He conceived the idea of measuring the tides produced in two canals (really two pipes half filled with water) of about 500 feet long, extending one N. and S., the other E. and W. These tides are, of course, of a microscopic character, their range is of the order of one-hundredth of a millimetre, and they could only be detected by the refined optical methods which Michelson himself has devised. The observations, when plotted on a magnified scale, exhibit all the usual features of a tide-gauge record: the alternation of spring and neap tides, the diurnal and semi-diurnal lunar tides, and so on. The theoretical tides in the canals can, of course, be calculated with great ease, and the comparison led to the result that the ratio which the observed tides bore to the theoretical was about 0.69, being practically the same in both cases. The whole enterprise was as remarkable for the courage of its inception as for the skill with which it was carried out, and was worthy of the genius which has accomplished so many marvels of celestial and terrestrial measurement. The perplexing discrepancy in the results obtained by Hecker at Potsdam is no doubt to be explained by the attraction of the tidal waters in the not very remote North Sea, and by the deformation due to the alternating load which they impose on the bottom. In Chicago, near the centre of the American continent, these influences were absent.

The question may be asked: What is the precise degree of rigidity which is indicated by these observations, or by others which have been referred to? Various answers have been given, based on observations of the tides, of the lunar deflexion of the vertical, and of the period of the earth's Eulerian nutation, on which I have not touched. The estimates have varied greatly, but they are all high, some of them extremely high. That they should differ among themselves is not surprising. The material is certainly not uniform, either in its elastic properties or the conditions to which it is subject, so that we can only speak of the rigidity of the earth as a whole in some conventional sense. Larmor and Love have shown that all the information that can be gathered, whether from the tides or from the Eulerian nutation, can be condensed into two numerical constants. This leaves a large degree of indeterminateness as to the actual distribution of elasticity within the earth. It is at all events certain that in regard to tidal forces the great bulk of the material must be highly rigid.

In leaving this topic, it may be recalled that it was in this same connexion that Kelvin was led to initiate the method of harmonic analysis as applied to the tides, as well as to accomplish much brilliant mathematical work, the importance of which is by no means limited to the present subject. The whole theory of the tides and cognate cosmical questions afterwards became the special province of George Darwin; but after his death, work on the tides was almost at a standstill until it was resumed by Prof. Proudman and his associate, Dr. Doodson, in the recently established Tidal Institute at Liverpool. They have already arrived at results of great theoretical as well as practical interest.

Within the last twenty years or so, light has come on the elastic properties of the earth from a new and unexpected quarter, namely, from a study of the propagation of earthquake shocks. It is pleasant to recall that this has been largely due to efforts especially fostered, so far as its means allowed, by the British Association. To John Milne, more than to any one else, is due the inception of a system of widely scattered seismological stations. The instruments which he devised have been improved upon by others, notably by Galitzin, but it is mainly to his initiative that we are indebted for such insight as has been gained into the elastic character of the materials of the earth, down, at least, to a depth of half the radius. It may be remarked that the theory of elastic waves, which is here involved, was initiated and developed in quite a different connexion, in the persistent but vain attempts to construct a mechanical representation of the luminiferous ether which exercised the mathematical physicists of a generation or two ago. It has here at length found its natural application.

One of the first problems of seismologists has been to construct, from observation, tables which should give the time which an elastic wave of either of the two cardinal types, namely, of longitudinal and transverse vibration, takes to travel from any one point of the earth's surface to any other. It has been shown by Herglotz and Bateman that if these data were accurately known it should be possible, though naturally by a very indirect process, to deduce the velocities of propagation of the two types throughout the interior. Such tables have been propounded, and are in current use for the purpose of fixing the locality of a distant earthquake when this is not otherwise known. They are, however, admittedly imperfect, owing to the difficulty of allowing for the depth of the focus, which is not always near the surface, and is sometimes deep-seated. This uncertainty affects, of course, the observational material on which the tables are based. Some partial corrections have been made by Prof. Turner, who almost alone in Great Britain, amidst many distractions, keeps the study of seismology alive, but the construction of accurate tables remains the most urgent problem in the subject.

Taking the material, such as it is, however, the late Prof. Knott, a few years ago, undertook the laborious task of carrying out the inverse process of deducing the internal velocities of the two types of waves referred to. Although it is possible that his conclusions may have to be revised in the light of improved data, and, it may be, improved methods of calculation, they appear to afford a fairly accurate estimate of the wave velocities from the surface down to a depth of more than half the earth's radius. Near the surface the two types have velocities of about 7.2 and 4 km. per second, respectively. These velocities increase almost uniformly as we descend, until a depth of one-third the radius is reached, after which, so far as they can be traced, they have constant values of 12.7 and 6.8 km. per second, which, by the way, considerably exceed the corresponding velocities in iron under ordinary conditions. The innermost core of the earth, *i.e.* a region extending from the centre to about one-fourth of the radius, remains somewhat mysterious. It can certainly propagate condensational waves, but the secondary waves are hard to identify beyond a

distance of 120° of arc from the source of disturbance. Knott himself inferred that the material of the central core is unable to withstand shearing stress, just as if it were fluid, but this must at present remain, I think, uncertain.

It should be remarked that the wave-velocities by themselves do not furnish any information as to the elasticities or the density of the material, since they involve only the ratios of these quantities. The relation between the two velocities is, however, significant, and it is satisfactory to note that it has much the same value as in ordinary metals or glass.

It is to be regretted that at present so little is being done in the way of interpretation of seismic records. Material support in the way of more and better equipped stations is certainly needed, but what is wanted above all is the co-ordination of such evidence as exists, the construction of more accurate tables, and the comparative study of graphical records. These latter present many features which are at present hard to interpret, and a systematic comparison of records of the same earthquake obtained at different stations, especially if these are equipped with standardised instruments, should lead to results of great theoretical interest. The task will be a difficult one, but until it is accomplished we are in the position of a scholar who can guess a few words in an ancient text, possibly the most significant, but to whom the rest is obscure.

Even on this rapid review of the subject, it should be clear that there is an apparent inconsistency between the results of two lines of argument. On one hand, the thermal evidence points to the existence of a high temperature at a depth which is no great fraction of the earth's radius, so high indeed as to suggest a plastic condition which would readily yield to shearing stress. On the other hand, the tidal arguments, as well as the free propagation of waves of transversal vibration at great depths, indicate with certainty something like perfect elasticity in the mathematical sense. The material with which we are concerned is under conditions far removed from any of which we have experience; the pressures, for example, are enormous; and it is possibly in this direction that the solution of the difficulty is to be sought. We have some experience of substances which are plastic under long-continued stress, but behave as rigid bodies as regards vibrations of short period, although this combination of properties is, I think, only met with at moderate temperatures. It is conceivable that we have here a true analogy, and that the material in question, under its special conditions, though plastic under steady application of force, as for example centrifugal force, may be practically rigid as regards oscillatory forces, even when their period is so long as a day or a fortnight. But beyond that we can scarcely, with confidence, go at present.

I have chosen the preceding subject for this address, partly because it has not recently been reviewed at these meetings, and also for the opportunity it has given of urging one or two special points. It is evidently far from exhausted—the loose ends have indeed been manifest—but this should render it more interesting. It furnishes also an instance, not so familiar as some, of the way in which speculations which appear remote from common interests may ultimately have an important influence on the progress of science. It is true that

the secular investigations into the form of the earth's surface have an importance in relation to geodesy, but certainly no one at the time of Laplace's work on this matter would have guessed that he was unwittingly laying the foundation of the whole mathematical theory of electricity. The history of science is indeed full of examples where one branch of science has profited by another in unexpected ways. I would take leave just to mention two, which happen to have specially interested me. It is, I think, not generally understood what an important part the theory of elasticity played in Rayleigh's classical determinations of the relative weights of the gases, where it supplied an important and indeed essential correction. Again, the mathematical theory of hydrodynamics, in spite of some notable successes, has often been classed as a piece of pure mathematics dealing with an ideal and impossible fluid, elegant indeed, but helpless to account for such an everyday matter as the turbulent flow of water through a pipe. Recently, however, at the hands of Prandtl, it has yielded the best available scheme of the forces on an aeroplane, and is even being appealed

to to explain the still perplexing problem of the screw-propeller.

To promote this interaction between different branches of science is one of the most important functions of the British Association, and differentiates it from the various sectional congresses which have from time to time been arranged. We may hope that this meeting, equally with former ones, may contribute to this desirable end.

Let me close with a local reference. The last fifty years have seen the institution of local universities and university colleges in many parts of Great Britain and of the Empire at large. Through these agencies the delights of literature, the discipline of science, have been brought within the reach of thousands whose horizons have been enlarged and their whole outlook on life transformed. They have become centres, too, from which valuable original work in scholarship, history, and science, has radiated. The University College of Southampton is now contemplating an increased activity and a fuller development. In this ambition it has, I am sure, the best wishes of us all.

Scientific Problems and Progress.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS OF THE BRITISH ASSOCIATION.¹

THE NEW IDEAS IN METEOROLOGY.

THERE have been great advances in the science of meteorology during recent years which have completely revolutionised our conception of the structure and mechanism of the atmosphere. Dr. G. C. Simpson devoted his presidential address to Section A (Mathematics and Physics) to a description of the chief of these advances, dividing his address into four parts, each dealing with one of the new ideas on which these advances are based.

(1) *The Thermal Stratification of the Atmosphere.*—By using the idea of entropy, Dr. Simpson showed that the atmosphere can be marked off into nearly horizontal shells which have the peculiar property that air which starts in any one shell cannot be transferred to any other shell and remain there in equilibrium unless heat is added or subtracted. Thus, in all atmospheric motion in which heat is neither added nor extracted, the air must travel along the shell in which it started. These shells act like physical restraints to the air, tending to prevent its moving in any but an almost horizontal direction. Occasionally the air contains sufficient water-vapour to supply, when it condenses, the heat necessary to pierce the thermal stratification, but these occasions are practically confined to thunderstorms and to the rain squalls in the doldrums. The thermal stratification of the atmosphere prohibits the ascent of warm air at the equator and descent of cold air at the poles which has generally been considered to be the cause of the general circulation of the atmosphere, on the analogy of a gigantic hot-water system.

(2) *The Mechanism of the Atmospheric Heat Engine.*—The old idea that the energy received from the sun is converted into the energy of winds by the air near the ground being warmed and rising, like the hot air in a chimney, is obviously unsound. The thermal stratification prevents this action in all but exceptional

cases. In place of this mechanism a new one is introduced. Masses of air from equatorial regions and from polar regions are brought side by side in middle latitudes. The cold polar air tends to subside and flow under the warm equatorial air which rises up the flank of the cold wedge which the polar air presents to it. When cold and warm air which were originally side by side react in this way, there is an appreciable lowering of the centre of gravity of the two masses taken together. Thus potential energy is released and appears as the energy of winds.

(3) *The Significance of Surfaces of Discontinuity in the Atmosphere.*—The surfaces at which relatively cold and warm masses of air meet and slide over each other as just described can easily be recognised on meteorological charts and by observations in the upper atmosphere. It is found that nearly all cloud is formed at such surfaces. Dr. Simpson discussed the conditions under which these surfaces of discontinuity can be maintained for long periods, and their significance in weather forecasting.

(4) *The Origin and Structure of Cyclones.*—The recent work of Bjerknes and Exner was described, according to which cyclones are formed where masses of air of polar and equatorial origin are brought together, and readjustment takes place in the manner described above. The old idea of a cyclonic depression being a kind of chimney drawing air in below and delivering it at the top can no longer be held.

These new ideas have had a far-reaching effect on the practical application of meteorology. Instead of the old empirical method of forecasting, the forecaster now has much more knowledge of what may be called the anatomy of a depression. He searches his charts for indications of the surfaces of discontinuity and examines the characteristics of the air masses to see whether they are of polar or equatorial origin. This has all resulted in greater confidence on the part of the forecaster, a confidence which is frequently justified by remarkably accurate forecasts.

¹ The collected presidential addresses delivered at the meeting are published under the title "The Advancement of Science, 1925," at 6s., or obtainable at the bookstall at Southampton by members at 4s. 6d.

THE CHEMISTRY OF SOLIDS.

IN his presidential address to Section B (Chemistry), Prof. C. H. Desch shows that the wonderful progress of physical theory in recent years has brought about a tendency to treat chemistry as a deductive science, the reactions of elements and compounds being deduced from the electronic constitution of their atoms. The chemical hypotheses of atoms, of molecular structure, of the benzene ring, of tetrahedral carbon, and of the periodic classification were devised in order to explain purely chemical observations, without reference to questions of ultimate reality, but modern physical investigations have shown them to represent Nature far more closely than their authors had supposed. This result should encourage chemists to continue on paths which have led to success before, rather than to base further work purely on an application of physical theory. The teaching of chemistry suffers from excessive and premature specialisation.

Attention is directed in particular to a comparatively neglected field of research, that of the chemistry of solids, by which are meant crystals and aggregates of crystals. The X-ray method has demonstrated the arrangement of atoms in crystals, and their mechanical properties have been extensively studied, but the relation between these and their chemical behaviour is obscure. The complication due to the unknown properties of the intercrystalline boundary may be eliminated by the use of single crystals, several of the metals having been prepared in this form. Reactions within a solid require the possibility of diffusion for their completion, and the evidence on this question is reviewed by Prof. Desch, as are the reasons for the variations of habit among crystals. Attempts which have been made to determine the distribution of the solute atoms in a crystalline solid solution by chemical means have led to the conclusion that isomeric solid solutions are possible. The study of the chemical properties of solids has been carried furthest in metallography, but is of importance also to chemical industry and to petrology.

CULTURAL ASPECTS IN GEOLOGY.

PROF. W. A. PARKS, in his presidential address to Section C (Geology), expressed the opinion that it is sometimes thought that the sciences are purely utilitarian and materialistic; they have, however, a high cultural value also in that they induce contemplation and bring their devotees into touch with the infinite. Geology, by reason of its breadth and its historical aspect, is particularly serviceable to this end. In both the organic and the inorganic worlds a tendency to greater and greater complexity is observed—from a universe of hydrogen to a maximum of chemical complexity, from a vibrant particle of protoplasm to man. The great age of the earth, probably 2,000,000,000 years, is a promise of still further duration, and the steady upward tendency of life is a promise of further development in the same direction.

Despite great geological changes, there have always been land and water, due to a marvellous nicety of adjustment between destructive and reconstructive forces. Similarly, although climatic changes have

been great, the temperature of the earth as a whole has been such that life has been possible from the earliest geological time to the present.

In the evolution of organisms, approximation to perfect adaptation is the herald of destruction. New races arise from less closely adapted stems, and the "missing links" are necessarily few and, owing to migration, are to be sought in stratigraphically oblique lines. Evolution is not brought about by some mysterious force acting on all organisms. The birth of a new phylum is a distinct event in time, and it does not bring about the extinction of the parent phylum. For example, sponges arose from Protozoa in the pre-Cambrian, and never since have the Protozoa fathered other than unicellular offspring.

Geological conditions govern most human activities, but those with a strong historical setting are particularly cultural. For example, a knowledge of the potential energy of Niagara Falls is not necessarily "culture," but that word may be applied to a recognition of the fact that Niagara Falls exist because some millions of years ago a layer of hard limestone was deposited over soft shales. The great principles of geology have had less effect on literature than might have been expected: this is particularly true of poetry. Among the major poets, Tennyson stands in first place in this respect. Strange to say, the principles of evolution and the great animals of the past seem to have inspired more doggerel verse than true poetry.

ORGANIC EVOLUTION.

IN his presidential address to Section D (Zoology), Mr. C. Tate Regan stated that his work on fishes has led him to the conclusion that the first step in the origin of a new species is the formation of a community, either with new habits or in a new or restricted environment. In Nature there is every gradation from morphologically identical communities to others so distinct that every one is agreed that they are well-marked species; thus the morphological discontinuity said to be characteristic of species is seen to be the final term of a habitudinal discontinuity that began with the formation of communities at first structurally similar. These ideas were illustrated by a detailed account of some species and communities of Salmonidæ.

The same principles apply to evolution in general; it has been adaptive; changes of structure have followed changes of habits, and especially changes of food and feeding habits. The origin and evolution of the neopterygian fishes illustrates well how modifications that were originally adaptive become historical; they persist, and become the basis for further adaptive modifications.

The natural selection theory is the only adequate explanation yet given of certain classes of facts; but it is a very unconvincing explanation of other classes, which lead to the conclusion that adaptive responses, repeated generation after generation, are consequently made earlier and more effectively. In the flat-fishes the cartilaginous bar above the eye that is going to migrate begins to be absorbed almost as soon as the fish is hatched, and while the fish is still externally symmetrical this bar becomes reduced to short processes of the otic and ethmoid cartilages, with a wide gap between them;

through this gap the eye migrates, so that when ossification takes place, one frontal bone is on the wrong side of its eye. This developmental history may be interpreted as the end result of a process initiated by the ancestral fish that first formed the habit of lying on one side, and tried to move the eye of the under side into a position where it could be of more use.

Many families of perch-like fishes, not at all closely related, have 24 vertebrae (10 praecaual and 14 caudal), and there is good evidence that this is a primitive percoid character. Here there is no variation, and therefore no material for selection, nor can any fish alter the number of vertebrae during its life by the way it swims. Yet it seems clear that this fixity has been broken through over and over again, and that the number of vertebrae has increased or decreased from 24 whenever it was necessary. Thus *Psettodes*, the most primitive flat-fish, structurally an asymmetrical perch, has 24 (10+14) vertebrae; it is piscivorous, and probably lies in wait and makes short dashes after fishes that come near enough. But other flat-fishes, which swim along the bottom with undulating movements, have many more vertebrae; the sole, for example, has about fifty. It seems that the muscular activities of a fish, its efforts to swim in a certain way, may produce a change in the number of muscle segments of its descendants. This may be condemned as a teleological speculation, but it is put forward as a hypothesis that fits the facts, and as preferable to the mutation hypothesis, which in effect states that it is only by accident that a structure has a function.

THE SCIENCE AND ART OF MAP-MAKING.

AFTER reference to Colonel Clarke as a distinguished citizen of Southampton, whose name is now to be commemorated by a tablet on the house where he lived, the president, Mr. A. R. Hinks, of Section E (Geography), expressed his lasting regret that Clarke's figure of the earth (1880) has not been chosen as standard by the International Conference at Madrid. With a glance at recent improvements in instruments Mr. Hinks discussed the modifications required in geodetic practice to cope with local attraction, referred to the intended reorganisation of time signals, and urged the establishment of British signals through the Imperial wireless chain. Dealing next with air-photographs and stereographic survey, he advocated reliance on ground stations, and an earnest attempt to apply the stereographic method to work on geographical scales. A summary of recent developments in map projections led to discussion of the International Map on 1/1,000,000, with the conclusion that its actual production should have been entrusted to a single establishment; that a smaller scale would have sufficed for much of the world; and that the work of the Permanent Committee on Geographical Names for British Official Use would be incomplete without a British map.

Turning then to the art of map-making, Mr. Hinks discussed the effect of multiple printings in colour, British pre-eminence in layer-colouring, and the need for some unproved mechanism for drawing or typing names. There has been a lamentable decline in the craftsmanship of both instruments and maps. The former dates from the application of the telescope, at an epoch when other crafts were at their highest point

of artistic merit. The decay in map-drawing came later, and may be repaired by diligent study and adaptation of early styles, rejecting the modern exaggerated use of distinguishing physical features by differences of lettering; but above all, avoiding sham medievalism.

THE MEANING OF WAGES.

IN discussing this extremely thorny problem in her presidential address to Section F (Economics), Miss Lynda Grier stated that no satisfactory theory of wages has as yet been formulated. Meanwhile, different interpretations of the word are accepted, varying with the aspects from which wages are considered. Wages are sometimes discussed as normal wages only, *i.e.* wages which represent the value of the work done under conditions of free competition. This value may be low, even when the work done is important and the workers do it competently, if there are many workers competing for a limited number of jobs and incapable of undertaking work of a different kind. When this is the case, the rest of the community gains by cheap services.

Frequently, however, wages are discussed as yielding an income which does or should maintain the worker. Up to a point the normal wage must supply sustenance in order to secure efficient workers. But it is not based on calculations of the length of the worker's life, of the cost of rearing him, of the size of his family, of the possibility of his death leaving a widow and children to be provided for. There is no necessity for employers to consider these things; few workers can afford to consider them. The normal wage takes account of the needs of the worker only when their satisfaction affects directly the supply or efficiency of labour. Beyond this point, needs are a weakness rather than a strength in bargaining.

Wage payments may be raised above the normal rate when demand for the product of labour is inelastic. In general, however, they can only be so raised by limiting the number of workers employed; the normal wage being the price at which all workers belonging to a particular grade can be employed in the occupations to which they are admitted. Attempts, legislative and non-legislative, to stretch wages to cover expenses not reckoned in normal wages are made at the risk of unemployment. Additions to low wages may be made with justice, since cheap labour which is not bad labour may provide cheap goods and since the worker is often not responsible for the cheapness of his labour. Moreover, all admit the necessity for some redistribution of wealth; but redistribution of wealth made in the name of wages may lead to a bad distribution of labour.

FIFTY YEARS' EVOLUTION IN NAVAL ARCHITECTURE AND MARINE ENGINEERING.

SIR ARCHIBALD DENNY, in his address to Section G (Engineering), traced the rise in the steam pressures used in marine engineering, and the passing from the simple to the compound engine, and from that to the triple and quadruple, which were practically universal in 1897. The appearance of the little *Turbinia* at the Spithead review in 1897 heralded a revolution in marine steam practice, which was at once embodied in the order placed by the Admiralty

in 1898 for the torpedo-boat destroyer *Viper*, and later in the mercantile marine, by the commissioning of the *King Edward* in 1901.

At first applicable only to the faster vessels, in 1909, after the conversion of the *Vespasian* from triple to geared turbine by Parsons, single gearing widened the scope of the turbine, and later double reduction gearing made it applicable to all types of sea-going vessels.

Dr. Diesel, who began developing the internal combustion engine for marine purposes in 1897, saw the fruits of his labours in trading vessels a few years before the War. Since the War, development has been exceedingly rapid, and indeed some enthusiasts claim that the days of the steam turbine are numbered for marine work. The reply of the steam turbine designer is higher steam pressures with superheat, pre-heating of the air to the furnaces, and stage heating of the feed water, etc.

There has been an enormous development in auxiliary machinery, both in the pursuit of economy and in providing for the greater comfort and convenience of the passenger and personnel. As to main engine power in any one hull, in 1875, 3000 I.H.P. was considered high, whereas now the highest in mercantile practice is 75,000, and in naval vessels 140,000 I.H.P. is found.

In the ship itself the changes in design and the growth in dimensions and draught have been many, while the developments in accommodation for passengers have been such that the third class of to-day travel at speeds and in a comfort which was not available to the first-class passenger of 1875, while now the first class have at their disposal all the comforts and luxury found "at home." Many changes in design were made possible when mild steel supplanted iron in the early 'eighties of last century, and present-day metallurgical researches make further advances probable.

Attention is directed to the various agencies which have assisted in the advances made, especially the influence of technical education, which in 1875, so far as workers in private works were concerned, was provided almost exclusively by evening classes under the guidance of the South Kensington Science and Art Department. The Admiralty, however, had much better provisions in the dockyards for their own students. The Admiralty training and the chairs in naval architecture which were later founded at three of our universities have had important influences on private works.

The regulations of the Board of Trade and the classification societies, and also the private and public research at the universities and at the National Physical Laboratory, especially in the Froude experimental tanks, of which there are now seventeen scattered throughout the world, have exerted important influences on shipbuilding. Finally, there are the technical institutions, such as the Institution of Naval Architects, which have had much to do with the development of design, while the effect of standardisation, under the guidance of the British Engineering Standards Association, is also discussed.

PRACTICAL ENGINEERING IN ANCIENT ROME.

DR. T. ASHBY discussed the remains of engineering works in Italy in his presidential address to

Section H (Anthropology), and stated that what appealed most of all to those who saw Rome in her prime were the aqueducts, the roads, and the drainage system. The Cloaca Maxima is ascribed by tradition to the Etruscan Tarquins, and (though nothing of the original structure is left) it still performs its functions, its splendid construction bidding defiance to the lapse of time: though, to our modern ideas, the direct discharge of sewage into the river seems dangerous.

Besides the drainage system, much attention was bestowed upon the regulation of the banks of the river and upon the bridges which crossed it. From there we pass naturally to the consideration of the road system, the nucleus of which dates from the beginning of Rome's history—of that wonderful network of roads which extended beyond Italy over the whole Roman Empire. Here, too (confining ourselves to Italy alone), we find a number of interesting and important engineering works. The Via Appia, the Via Traiana, and the Via Flaminia provide us with the best examples for study.

Turning last of all to the aqueducts, we find that the most important for our purpose are the four aqueducts which drew their supplies from the upper valley of the Anio, the Anio Vetus (272–269 B.C.) and the Anio Novus (A.D. 38–52), taking their supplies from the river the name of which they bear, the Aqua Marcia (144–140 B.C.) and the Aqua Claudia (A.D. 38–52), from springs which rise in the floor of the river valley. These aqueducts all required considerable restoration works, at more frequent intervals than one might have thought; and remains of the original channels of the two earlier aqueducts are rare, as indeed is to be expected, for they were built at a time when the danger of their being cut by an invader was still present.

As the course of these four aqueducts is often almost identical, the distinction of their remains was much facilitated by levelling operations carried out in 1915 by the late Prof. V. Reina; while Dr. Esther van Deman's researches on the chronology of the various types of construction employed in them are also of great importance. The remains are worth close study in detail; and the course of the aqueducts, which, when Prof. Lanciani's work was published in 1880, was still undetermined for several miles, has since been followed step by step, largely owing to his help.

These works of practical engineering seem to have been carried out by military engineers, who were at the same time civil architects—all of them Roman citizens, and for the most part Italians, not Greeks. The study of these works shows us that in this sphere, as in others, the Romans added very considerably to the sum of human achievement, and thus contributed in no small measure to make the condition of the human race what it is.

THE PHYSIOLOGICAL BASIS OF ATHLETIC RECORDS.

IN the records of athletics and of the various forms of racing there is a considerable store of accurate information as to the capacity of the human body for muscular effort, and the physiological basis of these achievements form the subject of Prof. A. V. Hill's presidential address to Section I (Physiology). The most complete collection of such information is to be

found in the "World's Almanac and Book of Facts," published by the *New York World*; similar, though not so extensive information, is to be found in Whitaker's Almanack. The manner in which athletic records can be explained by, and can be used to illustrate, physiological principles is best shown by plotting graphically the average speed at which a race is run as a function of the total time occupied in the race. In this way, for the various types of muscular effort involved, we may construct curves for the ideal individual, showing how long an effort of any required intensity can be maintained. For the shorter durations of effort, say up to twenty minutes, the form of the curve may be explained simply on the ground of the supply of oxygen, actual or potential, available to the competing individual. The muscular system works like an electrical storage battery in the sense that severe exertion may be undertaken for a time at the expense of oxidation (*i.e.* recharging) occurring afterwards in the recovery process. For anything but the shortest races, however, the amount of oxygen available in the contemporary supply through lungs and circulation is also of importance.

The following cases are considered: running, men and women; swimming, men and women; walking, rowing, bicycling, skating, and horse-running. Of these, running and swimming are almost precisely similar in their general relationships: both represent extremely rapid and violent exertion. Rowing, bicycling, and horse-running are different: the two former certainly, the latter probably, because the same extreme violence of exertion is not possible as in running and swimming. For efforts of greater duration, as in skating, bicycling, and in running and walking long distances, the determining factors are quite different from those concerned with the immediate usage and supply of oxygen. Here other types of fatigue, of a nature less understood at present, are at work.

The importance of skill in movement is discussed, and it is pointed out how the curve relating oxygen requirement to speed of movement gives a full and complete account, for any given individual, of the skill which he exercises in movement at any speed: the greater the oxygen requirement, the less the skill. Given a sufficient oxygen intake and a sufficient capacity for running up an oxygen debt, the chief factor in athletic effort of anything but the shortest duration is the skill and economy with which it is carried out. For the very short effort, economy is of less importance; the essential thing is to attain the greatest possible output of energy. Quite astonishing amounts of power are exerted by athletes in violent efforts of short duration.

SOME ISSUES IN THE THEORY OF "G" (INCLUDING THE LAW OF DIMINISHING RETURNS).

In his presidential address to Section J (Psychology), Prof. C. Spearman treated of certain points in a theory which has become known as that of two factors or of "g." According to this, every different ability of any person can be resolved into two factors, of which one is always the same but the other always independent; the factor always the same is intimately connected with what is commonly called "intelligence."

The proof falls into three distinct phases. The first

is to ascertain what are the conditions under which the measurements of any ability admit of such division into two factors. The second is to find where, if at all, these conditions are actually fulfilled. The third and last phase is that of supplying the factors with some serviceable explanation; the hypothesis which at present seems most helpful is that the "g" measures some particular form of "energy" derived from the whole cortex of the brain. Recently, the first phase was greatly advanced by discovering a new and much improved criterion of the divisibility called the "tetrad-difference." This has now been applied to the results of an actual experiment which furnished 3003 of these tetrad-differences. The median value of these as predicted by the criterion was 0.061; that actually found came to 0.062.

The second part of Prof. Spearman's address discussed the fact that in some abilities the "g" is predominantly influential, in others the "s." Now, evidence has been brought to show that the more any class of persons is well endowed with "g," the smaller becomes the influence of "g" as compared with "s." It would therefore seem as if the more energy is available already, the less advantage accrues from further increments of it. An interesting parallel to this is the economic law of diminishing returns.

In the third part of his address, Prof. Spearman showed that a great number of abilities, since they are dominated by the influence of "s," vary independently from one individual to another. The inference can be made that in respect of the great bulk of these abilities, every individual will tend to be near the average; a fair number will be distinctly above this, and a fair number below; at the extreme ends of the frequency distribution will lie a very small number of performances for which the individual is, on one side a genius, and on the other an idiot. To find out where the genius of each person lies is a work that seems likely to have extremely important results, educationally, industrially, and even socially.

THE PHÆOPHYCEÆ AND THEIR PROBLEMS.

THE Phæophyceæ or brown algae present a wide range of plant forms; in regard to external form and structure the higher members are the most highly differentiated of the Thallophyta, while in size they exceed greatly any green or red alga. In their reproductive schemes and life-histories they show striking differences, although the uniformity of their motile reproductive cells, the similarity of the colouring matter, and the products of assimilation indicate their descent from a common stock.

According to the presidential address to Section K (Botany) by Prof. J. Lloyd Williams, interest in the group has been much increased by recent work and also by Dr. Church's memoirs on the marine origin of the land flora. Much work has been done on the various bodies found in the Phæophyceæ cell, but the disagreement between investigators as to the nature, origin, and even the functions of these bodies, shows the need for further research. A similar state of affairs prevails with regard to our knowledge of the reproductive organs. The group, with its very divergent reproductive methods, is good material for a re-discussion of the theory of "alternation of genera-

tions," the various types ranging from Pylaiella, with fluctuating alternations of gametophyte and sporophyte, to Fucus, which is variously described as showing (a) alternations with extreme reduction of the gametophyte, (b) nuclear alternation of generations, and (c) no alternations at all, the plant being a gametophyte.

The address concluded with an appeal for increased study of the physiology and ecology of the brown seaweeds. No survey is available of the marine algæ of Great Britain, and there is also great need of an up-to-date English manual of the group.

THE WARP AND THE WOOF IN EDUCATION.

EDUCATION depends on a plan which includes the organisation and so much of the curriculum as is determined by the State, or by any other body in whom power is vested, and on the even more important contributions made by the teachers and by all the influences that surround the growing personality. The former is, according to Dr. W. W. Vaughan in his presidential address to Section L (Education), like the warp, the latter like the woof of the loom on which any fabric is woven.

The warp is at present probably too complicated, certainly too uniform, and it must remain too uniform so long as the State, for what were once quite good reasons, feels bound to define closely the powers of the local authorities, the boundary lines between education at different ages and of different sorts, and the limits of any city's or district's aspirations. What is now needed is that geographical units of reasonable size and homogeneity should be allowed to make real experiments, to set up warps of their own devising, receiving from the State in the way of grant what the State can afford to give and being allowed then to work out for that community a scheme of public education for the child, for the youth, and even for the man or woman.

In order that this may be done, we must get rid of some prejudices and some ideals that have been haunting us or are beginning to haunt us. One is that any extension of the school age must be uniform—applying to all children and to all places—another is that all are equally capable of fruitful education, another is that education cannot be won—and best won for some—by close contact with work that brings a livelihood, another is that education is to enable its recipients to have a happy leisure rather than to find happiness in daily work. The bogies, too, of wasted ability and thwarted genius must not be allowed to terrorise us. By all means do all that is possible—more indeed than is *done* now—to prevent waste, but do not let us be morbid in our fear of waste. Excellence depends on waste. Our careful precautions against waste lead to mediocrity.

The woof at which teacher or parent or employer or public opinion is always working depends on a more understanding co-operation between all those and all citizens too. For their goodwill alone can create the material circumstances in home and street that will prevent the influence of school being nullified by the influences that assail the impressionable mind in the hours of work, of leisure, and of recreation.

It is this co-operation that we teachers must ceaselessly implore and boldly claim.

THE MINERAL ELEMENTS IN ANIMAL NUTRITION.

IN his presidential address to Section M (Agriculture), Dr. J. B. Orr states that during the past half-century an increasing number of workers have become interested in the rôle played by inorganic salts in nutrition. Eight or nine of the mineral elements, *e.g.* calcium, phosphorus, potassium, etc., are known to be essential constituents of living matter. Iodine, manganese, fluorine, copper, zinc, and some others are found in traces. The presence of these was at one time thought to be accidental; it is now believed, however, that most, if not all, are essential constituents of the body.

The beginning of life-processes lies in the action of radiant energy on inorganic salts. The carbon atom is harnessed as the most suitable vehicle for conveying the chemical energy formed. The complex carbon-containing compounds, which have been regarded as the fundamental organic substances, are really secondary developments to secure that degree of stability and complexity required for the evolution of higher forms of life.

In the animal body, changes in the concentration of the inorganic ions in the circulating fluid are correlated with changes in functions of the organs. Thus, all the organs regulated by the central nervous system depend for the integrity of their function upon the maintenance of definite ratios of calcium, potassium, and sodium in the fluids within the nerve tissues. The classical experiments of Ringer on the perfused heart show that minute changes in the concentrations of calcium or potassium in the perfusing fluids have a profound effect on the activity of the heart. It is probable that the function of the bones in regulating the supply of mineral elements to maintain the "physiological balance" of the body fluid is as important as the more obvious one of providing a rigid framework. It is probably more fundamental, for when the available mineral matter is insufficient to maintain both the physiological balance in the blood and the rigidity of the skeleton, it is rigidity which is sacrificed.

When, for prolonged periods, the diet contains deficiencies or excesses of mineral elements greater than can be dealt with by the regulating mechanisms of the body, pathological conditions develop. It has been found that these occur not infrequently under modern conditions of intensive production in animal husbandry. Attempts to adjust the mineral content of diets by the addition of inorganic constituents that appear to be deficient meet, in many cases, with a marked degree of success. In the present stage of our knowledge, perfect adjustment is impossible. We need further information with regard to the amounts of each of the essential mineral elements required under different conditions, and the influence of the factors such as the "balance" of the diet and ultra-violet irradiation on the assimilation of mineral elements.

Valuable results are likely to be yielded by investigations on the interactions of colloids and inorganic ions, on the influence of the electrical charge and chemical characteristics of the ion on these reactions, on the effects of radiant energy on the processes associated with mineral metabolism, and on the relationship of these to both normal and pathological processes in the body. In this region there seems to lie the key to the solution of many obscure problems, both of the normal metabolism of health and of the abnormal metabolism of disease.

Cotton-Breeding, Plant Physiology and Agriculture.

KNOWLEDGE of the cotton crop presents a curious antithesis to that of wheat. The effects of environment are better analysed and understood for cotton than for most crops, but whereas the genetic study of wheat is classical, that of cotton is fragmentary. About cotton we have practically no "useless" genetical information, such as may suddenly turn out to hold the key to commercial difficulties, and a recognition of this ignorance has been a factor in founding the new Empire Cotton Experiment Station in Trinidad. So far, this lack of knowledge has mattered less than it might have done, because Nature provides the cotton-breeder with ample occupation in merely isolating pure lines from the complex population which arises from the small amount of natural crossing in cotton. Thus, almost no successful application of synthetic genetics has been made to cotton, except by Leake.

A further complication of cotton-breeding (and a further justification of the Trinidad scheme) lies in its inability to be a self-contained science. The cotton-breeder has one foot in the physiologist's camp so long as he deals with the inheritance of dimensional characters; and while cotton is grown as a paying crop for spinning purposes, its dimensional characters take practical precedence of all others. This may or may not be the right attitude, but at least we may be sure that the dimensions—if inherited at all as such—are not inherited in isolation. The writer had some glimmering of this when, in the dawn of Mendelism, he started to record every recordable characteristic in one hybrid cotton; his simultaneous observation that there were about two dozen chromosomes was damping to enthusiasm, even in those pre-Morgan days, and the study of dimensions led him by insidious paths into physiology. There is, of course, no antagonism between genetics and physiology in cotton; rather they are much too intimate, so that their disentanglement is quite difficult.

Some illustrations of this intimacy are provided by the report from the Bombay Presidency of the second annual Conference of Plant Breeders held at Surat last spring. The very first group of papers not only dived into physiology, but came out on the other side, with a discussion on the probable error of field experiments, an omnibus subject if considered for what it really contains, but yet an end in itself for the economic side of agriculture. The reputed instability of certain improved varieties when grown by farmers was next discussed; and, though traced to the obliteration of small superiorities by local conditions, it led to a

recommendation that "adaptability to a large range of conditions should be the ideal in breeding improved races." It is more than doubtful whether this ideal can be realised. Most species which adapt themselves to a wide range of conditions are complexes of elementary species, between which natural selection takes place on establishment in any fixed environment. When such elementary species, or similarly pure lines of cotton, are tested for various environments, they have been found by the writer to exhibit most decided local preferences; in one pair of Egyptian strains the long staple became short in the Sudan while the short became long; in another pair the yields crossed over when moved from Cairo to the cooler sea-board. Indeed, it seemed that if flexibility were wanted very badly, without abandoning the control of production-quality which pure lines give, then it would be necessary to issue blended seed containing more than one pure line. The suggestion may seem absurd; but with cotton it is in any case essential to have a seed-renewal system, so that after the lapse of some three years, when the blended strains have intercrossed to a serious extent, the bulk seed supply would be due for renewal from the pure stocks. It may be possible with some plants to eat one's cake and still possess it intact, but with cotton at least there seems to be a choice between putting stable pure lines into their appropriate environment or continuing to endure the inconvenience of unstable but plastic commercial "varieties."

A discussion on the possibility of standardising testing methods for different crops was held at Poona but does not seem to have been very helpful, as abridged in the report now before us. Testing as testing is a rather futile process, whether of crop yield, yarn elasticity or metal hardness; it can aim only at establishing comparable facts, which are incidentally and inevitably numerical. There is no test result known to the writer, in agriculture or textiles or engineering, for which he would not be glad to substitute an understanding of why the result was obtained. Without such understanding, even if imperfect, some of the factors implicit in the test method will escape control, and the comparability of the facts established will thereby be invalidated. More analytical, and much more physiological, was an account by Mr. M. L. Patel of the competitive effects of adjacent plants in the crowd of a field crop, and the differences from one strain to another in this respect.

Genetics as such does not appear until half-way through the Conference, with a note on natural crossing, also by Mr. Patel. The desirability of mass selection was then seriously questioned, though apparently without reaching the only definite conclusion possible,

namely, that while mass selection is the first thing to do, it is also the worst thing to do, and is simply a stop-gap expedient. We would like to hear more of the figures on which the next discussion was based, namely, "Acclimatisation and the Adaptation of Newly Imported Seeds." Few topics have been more thoroughly disintegrated than this by mere convictions, and any facts are of value. The Conference did not commit itself in its conclusion, which wags a reactionary tail; it considered that "acclimatisation was a fact and that it might be (1) selection by climate of like individuals from an obvious mixture, and (2) selection by climate of a physiologically suitable race from a variety apparently pure for all external characters, or the gradual adjustment of some individuals of a variety to a new environment, and that it is desirable to consider each case on its own merits."

It is clear that the plant breeders of the Bombay Presidency do not lack material for investigation, nor are they geneticists only. So far as can be judged from a brief report, it would seem that a useful service could be rendered to his fellows by some one who would dissect the complex story of plant-breeding into unit assertions—even if they were wrong—and definitions. To have two main meanings and several subsidiary ones, some mutually contradictory, for a single word like "acclimatisation," does not facilitate discussion with fellow-workers, or afford explanation to the outsider.

W. L. B.

Science at Oxford.

Early Science in Oxford. By R. T. Gunther. Vol. 3. Part I.: The Biological Sciences; Part II.: The Biological Collections. Pp. xii + 564 + 64 plates. (Oxford: The Author, Magdalen College, 1925.) 42s. net.

THIS splendidly produced and entertaining volume is the third of a series which Mr. Gunther has devoted to an account of the historic remains of scientific Oxford. They stand as a permanent memorial of the subject of which they treat. Like its predecessors, this volume is in the form of a catalogue, in which each heading is provided with a short introduction. It differs from the generality of catalogues in being extremely readable, and in the capacity that its author exhibits to lead the reader from point to point. Mr. Gunther is to be heartily congratulated on an achievement involving a most unusual combination of persistence, scientific knowledge in many departments, self-devotion, and literary skill and charm.

The history of science has two aspects, complementary one to the other. It may be treated from the point of view of the development of scientific ideas, the historian tracing these ideas in reference to one another and to

the cognate thought of the successive ages. This is the philosophical or psychological approach. The exponents of this method usually pay but scant attention to the "false starts" in science, they ignore almost entirely the by-paths of the subject, and are more interested in methods and results than they are in the men who use one or attain the other. On the other hand, the subject may be treated from the point of view of biography or of local history. This is the antiquarian or archaeological method. In the ultimate analysis it is philosophically indefensible, since the scientific process, of its very nature, demands that the search for truth must be carried on without prejudice to persons, and that truth, when found, must be taken for what it is, without regard to its origin. Science is the great leveller. Should she bow the knee to any idol, whether of the tribe, the cave, the market-place, or the theatre, she loses her divine right. But the antiquarian method is nevertheless very useful in another sense. By it alone can we learn of the social and intellectual environment in which science yields effective fruit, and—what is no less important—by it we can learn of some of those insidious factors that render science sterile. This knowledge is of evident practical application.

Mr. Gunther is an eminent exponent of the antiquarian method of scientific history. The value and interest of his results are undeniable. They have been justly greeted in his own University as containing a hitherto unwritten chapter in its long and varied history. Mr. Gunther is a genial and optimistic writer, a very loyal son of his *alma mater*, an admirable *raconteur* with a good eye and ear for the bizarre and ridiculous, which, however, never permit an interference with his enthusiasm for what is high and great. Nevertheless, reflection on the results of his work does not summon up thoughts that are consoling or cheering.

After enjoying these volumes, the contemplative reader will naturally ponder the end of all the endeavour that is there related. Since the Revival of Learning, four hundred years ago, a great University has been equipped with great endowments assigned to scientific ends. What have been the results? Let us discount the "amateur" who has ever borne an honoured place in British learning, but whose debt to his university has ended with his literary training. Let us put him aside and make a proper balance sheet: on one hand the endowments for scientific instruction, on the other the scientific achievements of those who have held, in this great and ancient University, the offices for the imparting of that instruction. Mr. Gunther rightly ends his book with a "Table of Succession of the Scientific Professors." It is the summary of the whole book, and is mournful reading. On the credit side a few really great scientific names will be discerned,

among them several of the founders of the Royal Society. But apart from the last generation or two, and excluding this limited number of brilliant exceptions, the succession is one of scientific nonentities, mostly men who do not take even a secondary place in the annals of science.

These fine volumes of careful studies thus bring out a fact that all interested in national education should take to heart. It is that the best manner of obtaining scientific results can by no means be easily determined. A very complex psychological question is involved. Pious founders in the past and in the present have often thought that they could obtain good results by mere monetary gifts to some particular department of learning. Men with affectionate memories of this school or that college seek to link the glory of an ancient foundation with that pure search for knowledge that can never be the property of a class or institution. These volumes show how much of this seed, thus strewn with careless and generous, if ignorant enthusiasm, has fallen and will fall on sterile ground.

The fact is that the production of an effective scientific atmosphere depends in the end on neither endowments nor institutions nor even good will, but on the intellectual outlook of society as a whole. The lesson is to help to create that outlook and the rest will follow naturally. The arrogant aloofness of the classical spirit of Oxford for centuries separated it from many of the movements that stirred the pulses of the people of England, and among them was the great scientific movement, the most important intellectual event of the last eighteen hundred years. Shame it is on our humanity and to the memories of its creators, the great minds of Greece and Rome, to call such a spirit "humanism"! The price—and it is a heavy one—has been most surely paid for being the home of lost causes. That phrase must not be lightly glossed as a mere joke or epigram. It is a diagnosis of a grave and deeply seated spiritual malady. From it Mr. Gunther's University emerged into convalescence only in quite modern times. His volumes will be read by posterity, but we believe that they will be read for the account that they contain of the course and symptoms of a very deadly disease.

The Technology of Glass.

A Text-book of Glass Technology. By F. W. Hodkin and A. Cousen. Pp. xxiii + 551. (London, Bombay and Sydney: Constable and Co., Ltd., 1925.) 42s. net.

FOR several years the glass industry of Great Britain has suffered from the lack of an up-to-date and authoritative text-book upon the technology of glass, but the deficiency has now been made good by

Messrs. F. W. Hodkin and A. Cousen. All interested in glass will welcome the recently published compilation of these two authors, and the industry owes them a debt of gratitude for such a masterly exposition of their subject, which covers the whole field of glass manufacture. Acting with admirable forethought, they have not stressed any one side of this manufacture above another, and throughout the work they have adhered to their determination as stated in the preface: to attempt no encyclopædic survey, but to allow the book to take the simpler form of a general introduction to the study of glass technology. In this they are to be commended, because the book becomes as valuable to the beginner as to the expert. The latter may indulge his desire for more detailed knowledge by reference to original papers and to books specified in a well-arranged bibliography and in copious footnotes, whilst the beginner will find each chapter easy to assimilate, there being no extraneous matter to confuse him.

The general arrangement of the volume will meet with approval, and it shows the stamp not only of experienced teachers but also of men who have a wide practical knowledge as well. Commencing with a chapter upon the historical development of the glass industry, the work naturally divides itself into sections upon physical properties, raw materials, fuels, refractory materials, furnaces and glass-making processes. No matter of importance is neglected, and each chapter is a mine of information upon the subject with which it deals. To those whose knowledge of chemistry is limited, Chap. ii. dealing with the basis of glass technology will be found helpful, as it indicates in a simple manner how glass is produced from raw materials. Chaps. iii., iv., v. and vi. upon the physical properties of glass, whilst of interest generally, are of particular import to those in whose domain lie the devising of new glasses and the improving of old. The question of thermal endurance is rightly stressed as this property is so important in every type of glass. The various factors which determine this endurance are also fully discussed. In this connexion, it would have increased the value of Table xv. to have included with the compositions of the glasses shown, the thermal endurance values calculated from the Winkelmann and Schott relation. However, the reader will find pleasant exercise in supplying the values for himself, using the various tables provided, which deal with density, tensile and crushing strength, elasticity, hardness, specific heat, expansion and the like. It may be said regarding these tables that one deprecates the omission of the values of Winkelmann and Schott for the elasticity factors of the various constituents of glass (see *Ann. d. Phys. u. Chem.*, 1894, p. 711, and 1897, p. 122).

One of the most valuable chapters in the book

(Chap. vi.) deals with the question of the durability of glass, and it provides a very thorough survey of the knowledge accumulated upon this important subject. A more detailed account of the apparatus used in testing for durability, together with diagrams of such apparatus, would not have been out of place and would have been found useful by manufacturers desiring to apply durability tests to their ware. In comparing the effect of sodium oxide and potassium oxide upon durability, "Peddle's generalisation" might well have been included, namely:

"In alkali—RO—silica glasses where RO is the oxide of calcium, barium, strontium, magnesium, zinc or lead, when the total alkali present is less than 20 per cent., a glass containing both alkaline oxides will be less soluble and more durable than the glass containing the same amount of alkali as sodium oxide or potassium oxide alone. This is true whatever amount of silica or RO is contained in the glass."

The raw materials of the glass industry are dealt with in Chaps. vii.-xii. The account given will be found full and up-to-date, in particular the pages dealing with the treatment of sands and the storage and mixing of batches. A special feature of this section is the tabulating of more than 100 batches for glass-melting, the mixtures given ranging over most of the best known types. To those who find difficulty in the calculation of batches for glass, Chap. xi. will appeal with especial force because the whole question of such calculations is treated in a very comprehensive manner. Purists will quarrel with the authors when they write " $\frac{1}{2}\text{K}_2\text{O}$," etc., thereby implying the "half molecule of a compound," but the expression may perhaps be tolerated in this chapter as it simplifies calculation considerably.

The authors deal with combustion and the evaluation of fuels in a very lucid manner, all the data being well marshalled and easy to assimilate. Chapter xiv., upon combustion, is rendered all the more valuable by the inclusion of typical calculations, and these are treated in a fashion which commands admiration. Throughout the volume, indeed, one cannot help being impressed by the facile manner in which calculations are worked out. In view of the increasing recognition of the value of temperature control in all glass-working processes, Chap. xvii., upon pyrometry, will arouse interest, and in it will be found a full account of the various devices for registering temperature in a glass works.

The sections of the work that will appeal most to actual manufacturers are those upon producers, refractories and furnaces. Chap. xix., dealing with producers, has only to be read to be appreciated, for it is a veritable storehouse of information. Pride of place among the four chapters (xx.-xxiii.) upon refractory materials must be given to that which

describes the manufacture of glasshouse pots and blocks, because of the series of fourteen photographs illustrating the production of a pot. Seven chapters in all (xxiv.-xxx.) are devoted to furnaces, and we have nothing but praise for the manner of treatment. Numerous diagrams and photographs enhance the value of these chapters, which deal in sufficient detail with many types of furnaces, lehrs, and so on, without being at all verbose, whilst the discussion is without bias. The principles of regeneration and recuperation receive full attention, and the respective merits and demerits of the two systems are emphasised.

The volume ends with nine chapters upon glass-making processes. This section will be of especial interest to the general reader as it serves to indicate the huge strides that have been taken during the present century in the manipulation of glass by machinery. The most modern processes are ably dealt with and a wealth of photographs and of diagrams is included. In this connexion it may be said that the whole book is admirably illustrated by more than 250 figures, many of them being full page in size.

The indexing will be found comprehensive, sections being devoted to name index and subject index, whilst a word of praise is due to the proof-reading, which has been very thorough. Very few errors will be met with in the text, and those of small importance.

Economy and Efficiency in House-Heating.

House Heating: a General Discussion of the Relative Merits of Coal, Coke, Gas, Electricity, etc., as alternative means of providing for Domestic Heating, Cooking and Hot Water Requirements, with Special Reference to Economy and Efficiency. By Dr. Margaret Fishenden. Pp. 296. (London: H. F. and G. Witherby, 1925.) 25s. net.

DR. FISHENDEN has provided one of the most interesting books that has ever been written on a most important branch of domestic science. Her work has been known for a considerable time to all those who are specially interested in the performances of domestic heating appliances, through valuable reports which have been issued from time to time by the Department of Scientific and Industrial Research. The contents of these reports have now been collected and expanded so as to give greater continuity and comprehensiveness of treatment, with the addition of critical historical matter, and a wide public owes a debt of gratitude to Dr. Fishenden for having undertaken the task, and having carried it through so well.

The book begins with a preliminary consideration of fuels available, their composition, and the methods of production of such artificial fuels as town gas and coke.

A brief summary of the position of electricity as a heating agent, and of the reports of the Electricity Commissioners in relation to power supply, terminates with the judgment: "At present, however, even the fact that most electric heaters give efficiencies of practically 100 per cent. theoretical, is not enough to counterbalance the low thermal efficiency and high cost of production."

Dr. Fishenden goes on to treat of the development of the modern sitting-room grate, and justice is done to Count Rumford, who was advocating at the end of the eighteenth century ideas applied in the modern fireplace, and to Dr. Pridgin Teale of Leeds, who enunciated detailed rules for the construction of fire grates, some of which are so generally adopted in the design of modern fireplaces that the author sets them out in full.

Then we begin to see the kind of thing that Dr. Fishenden has herself been doing in a paragraph headed "Fluctuations in the Rate of Burning of Coal Fires," accompanied by a number of diagrams indicating the variations in the intensity of radiation emitted from fires fed with coal, slack, and coke, stoked in different ways. A study of the distribution of radiation from open fires was carried out on the general plan adopted in the "Leeds" tests, described in the first and second Reports of the Joint Gas Heating Research Committee of the University of Leeds and the Institution of Gas Engineers. This chapter is very comprehensive. It is appreciative as regards the method employed by Prof. Boys in successfully burning gas coke on a flat firebrick hearth with an overhanging firebrick back, and the reverse of appreciative in dealing with the effect, or rather non-effect, of patent preparations on the efficiency of coal fires. The importance of providing draught regulation with coal fires is insisted upon, and the common error in the older open fireplace of drawing far too much air through the room is emphasised. The opportunity in installing a gas fire of realising a more efficient and economic arrangement in this respect is made very obvious. A corresponding treatment is then given to the development of the kitchen range, the survival of which is attributed to the fact that it can meet so many different requirements, although it functions so uneconomically with respect to any one of them. Dr. Fishenden's conclusion is: "It is probable that the independent boiler with open fire, with or without the addition of an oven, will gradually rise to a considerable degree of popularity, gas being used for cooking when no oven is included in the range."

The chapter on "The Development of Gas for Heating Purposes" is also very well done, and stress is rightly laid upon the ventilating effects of gas fires. In the discussion of room heating it is too often

forgotten that the fire and the flue into which it works are serving a double purpose, and that from the hygienic standard the ventilation is at least as important as the heating. Merely to warm the air in a room is insufficient, and in this lies the weakness of so-called "radiators" (which are mainly convectors), whether heated by steam or gas, and of nearly all the electric heaters.

An interesting chapter follows upon the use of gas for cooking purposes, in which the "Standard Gas Cooker" proposals of the Standardisation Committee of the National Gas Council are detailed, and the new gas cooker of Messrs Radiation, Ltd., with its semi-automatic controlling device, are both described along with more specialised devices, such as the Radiophragm heating introduced by Prof. Bone specially for toasting or grilling operations.

As regards the efficiencies obtainable in gas heating and cooking appliances, the results of the Gas Investigation Committee of the Institution of Gas Engineers and the University of Leeds in Britain, and those of the Bureau of Standards in the United States, are widely quoted.

Electricity for heating, cooking, etc., is given a chapter to itself, Dr. Fishenden pointing out that "modern electrical cookers, like electrical heaters in general, can be considered to owe their origin to the discovery of nickel-chromium high resistance wires," which stand long contact with air at high temperatures. Various types are discussed, and then in another short, but interesting, chapter the position of central heating by various methods is indicated and briefly discussed.

In many ways the most important and useful chapter of all is that which brings the book to a close, but it is not easily summarised. It is to be hoped, however, that this impartial and well-informed summary by a competent authority, who has given special attention to the subject, will be widely read, even by those who have not the time or perhaps the inclination to read the more detailed considerations of the preceding chapters. It is a statement and an expression of reasoned opinion which comes at a time when it is very much wanted, in the first place, because a combination of circumstances is persuading or compelling householders to find out what are the most economical, cleanly, and healthy methods applicable for carrying out the heating operations required in their homes, and secondly, because without such information it is only too likely that catch-words may take the place of principles in forming public opinion and inducing legislative action.

The reviewer does not mean that he would necessarily endorse in detail all the statements and conclusions made in this chapter, but he does regard it as an excellent attempt at summarising a very complicated

matter. Dr. Fishenden begins by taking the costs of different fuels which would be sufficient, if completely burned, to produce one therm (or 100,000 B.Th U.), and then, with reasonable assumptions as to comparative efficiencies, points out that "with coal at 50s. per ton, gas at 10d. per therm and electricity at 1d. per Board of Trade unit, an up-to-date open gas fire would cost about two and a half times as much as an open coal fire, whilst an electric heater would cost about five and a half times as much. But it must be clearly understood that in this comparison equivalent heating values during continuous running have been the basis, and no allowance has been made for the saving in labour effected by the use of gas or electricity as compared with coal." For intermittent use, of course, the conditions become much more favourable for the more easily controlled methods of heating. "In practice, owing to the fact that coal fires cost an appreciable amount to light, and involve a great deal of work in the carrying of coal, cleaning of grates, etc., gas fires for such periodic heating would generally prove to be decidedly cheaper than coal fires. And even electric heaters, on the relative costs which have been taken, would sometimes, by their convenience and adaptability, repay for the higher cost of the units used."

One of the most useful portions of this chapter is that in which the author considers in turn heating appliances for large and small houses and for cottages, discriminating wisely between the requirements of one and another. Her final sentence is "For almost every purpose which raw coal at present fulfils, smokeless domestic cokes would prove a satisfactory substitute, and used in conjunction with gas or electricity would enable all domestic heating, cooking, and hot water requirements to be carried out economically, with a complete absence of black smoke production."

One criticism the reviewer must make. This book is very well printed, and the diagrams are numerous and clear, but it is surely a book for which a large circulation should be sought, and the price asked will scarcely allow of that object being attained. JOHN-W. COBB.

The Morphology of Crustacea.

Studies on Arthropoda, II. By Dr. H. J. Hansen. (Published at the expense of the Rask-Ørsted Fund.) Pp. 176 + 8 plates. (Copenhagen and Berlin: Gyldendalske Boghandel, London: Constable and Co., Ltd., 1925.) 15s. net

SO long ago as 1893, Dr. H. J. Hansen published in the *Zoologischer Anzeiger* a preliminary paper on the morphology of the limbs and mouth-parts in crustaceans and insects. Many of the views adumbrated in that paper have since been adopted and developed by others, and some of them have been

further illustrated by the author himself in the course of systematic papers dealing with the varied groups of arthropods which he has studied. Now, after more than thirty years, we have the first part of the connected exposition of his morphological views, for which the earlier paper was to prepare the way. In this memoir, only the Crustacea are dealt with, the remaining divisions of the Arthropoda being reserved for a future part.

So far as it is not purely descriptive, Dr. Hansen's point of view may be said to be that of an idealistic morphology. He abjures phylogenetic speculation, and has nothing to say as to the structure of hypothetical ancestral forms. This was also the point of view of the great protagonist of Darwinism, whose centenary we have recently been celebrating. It was Huxley's opinion that "morphological generalisations . . . will remain true, so far as they are true at all, even if it should be proved that every animal species has come into existence by itself and without reference to any other." It may perhaps be doubted, however, whether even Huxley was able to keep his morphology quite untainted by evolutionary speculation. Try as we may, we cannot look at things with the eyes of the pre-Darwinians, but it is right that we should be reminded how much in our phylogenies is sheer guesswork and how little justified is the confident dogmatism of "Haeckelismus."

Dr. Hansen describes in great detail, and illustrates in a series of finely engraved plates, the chitinous exoskeleton of the mouth-parts and limbs in the main subdivisions of the class Crustacea. He brings much additional evidence in favour of the view, now accepted by many authorities, that the sympod (protopodite of Huxley) is typically composed of three, instead of two segments. In the thoracic legs of Decapoda he finds that an additional segment, first observed by Coutière and here termed "præischium," is often indicated, and he bases on this a new scheme of comparison of the segmentation of the legs in the various orders of the Malacostraca. In this scheme the position of the "knee," or main flexure of the limb, is assumed to remain constant throughout the sub-class. On this point it is perhaps permissible to doubt whether the evidence is quite conclusive.

Dr. Hansen has no doubt that the trilobites should be regarded as Crustacea, rejecting, probably with justice, the arguments against this view drawn from the absence of a shell-fold and the sessile condition of the eyes. He thinks it impossible that the limbs can have been articulated, in the way described by Raymond and Walcott, to downgrowths of the dorsal skeleton, and, indeed, such a mode of articulation would be without parallel among recent arthropods.

In dealing with the Cirripedia, the interesting suggestion is put forward that the so-called "mandibles" of the adult may be the maxillulæ, the mandibles being lost in the course of development. This point might well engage the attention of embryologists.

Great importance is attached to Geoffrey Smith's description of a biramous mandibular palp in *Paranaspides* as giving the clue to the interpretation of the palp in other Malacostraca. No subsequent observer, however, has been able to see a trace of the biramous condition in *Paranaspides*, and there can be little doubt that Geoffrey Smith was misled on this point.

Many other points of general morphological interest are discussed in the course of this memoir, which deserves the close attention of all students of the Arthropoda.

W. T. C.

Education of Chimpanzees.

The Mentality of Apes. By Prof. Wolfgang Köhler. Translated from the second revised edition by Ella Winter. (International Library of Psychology, Philosophy and Scientific Method.) Pp. viii + 342. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1925.) 16s. net.

PROF. KÖHLER'S book marks a distinct advance in comparative psychology, for he was able to study his chimpanzees in very favourable conditions of health and housing in Teneriffe. He also realised that these apes are characteristically social creatures and must be studied in companionship with their fellows. A chimpanzee is intellectually and emotionally bewildered if it is kept in solitary confinement. "It is hardly an exaggeration to say that a chimpanzee kept in solitude is not a real chimpanzee at all." Prof. Köhler's experiments were also marked by their critical carefulness. No emphasis is laid on single incidents; the crucial experiments were repeated many times. Generous descriptions were for the most part rejected.

The book gives abundant evidence of genuine intelligence or power of perceptual inference. Thus a chimpanzee will pile one box on the top of another to the number of four, in order to reach a banana fastened to the roof of the cage. In the course of a forenoon a clever chimpanzee discovered how to fit a short bamboo rod into the end of a longer and broader one, so that it was able to reach a prize lying beyond the bars. Even more striking was the prolonged biting at an unsuitable piece of wood so that it could be fitted into the bamboo rod, thus making a double stick. The apes often showed very precise observation, for example, of the spot on raked and featureless ground where they had seen some treasure

buried. They recognised their teacher or a companion after prolonged absence, though on the whole, out of sight is out of mind to a chimpanzee. A conspicuous feature was the restless inquisitiveness; it often seemed as if they liked trying for trying's sake. They would feed the hens with bread which they themselves were not fond of, and would watch the details of the pecking with great interest—obviously the beginning of chimpanzeeish ornithology. This they would prosecute by luring a hen close to the cage and then suddenly giving it a dig in the ribs with a stick. Very quaint was the appreciation of a hand-mirror and the passage to the use of other things as mirrors, such as pieces of metal or even a pool of rain-water, at which they would stare long and intently, just as if self-consciousness was dawning. Yet in spite of long-continued experiments, the apes never got away from the conviction that there was an elusive "other fellow" through the looking-glass. For him they would lie in wait and at him they would make many a sudden pounce!

The particular limitations of chimpanzees seem to be their poor vocabulary and their slight capacity for working with "images" in the mind. They solved many problems, such as those we have mentioned, but one condition of success is that they must be brought into circumstances where the factors that constitute the solution are all visibly given. They must have all the facts of the case within their visual range. The book seems to us a very valuable one: its net result is to show that chimpanzees are very ingenious within a narrow range.

Our Bookshelf.

The Production and Measurement of Low Pressures.
By Dr. F. H. Newman. Pp. 192. (London: Ernest Benn, Ltd., 1925.) 16s. net.

IN recent years the advance of physics, especially atomic physics, has required vacua of an ever-increasing perfectness; to this end a series of extremely ingenious methods and pieces of apparatus have been designed, most of which have only been developed after the fundamental principles underlying each of them were fully mastered. At the same time manufacturers have availed themselves of these improved methods, and it is now common practice that methods of exhaust of the most recent type are employed in the production of commercial articles which require to be exhausted to the very highest degree. In order to be able to measure such high vacua, gauges capable of such precise measurements have been developed, and it is, of course, only by advancing such means that the process of exhaust can be improved.

Prof Newman in his book has given a very good description on both parts of this subject; after a short historical résumé, he has given an excellent account of

all modern high vacua exhaust apparatus, which will certainly be of great use to all concerned in such work, and from a large number of tables (some of which possibly might have been better expressed as a curve) has afforded the physicist or the vacuum engineer a sound basis from which he will be able to choose the type of apparatus suitable to his work.

The effect of the size and length of connecting tubes on the rate of exhaust is dealt with and the importance of these factors is shown by a few examples. There is a chapter on "Sorption," giving a good résumé of the most important papers which have been published, after which comes an interesting chapter on "clean up," the process which plays such an important part in the modern methods of lamp and valve manufacture.

The second section of the book deals with the measurement of pressure. Here the different methods are fully described—each one being given space according to its practical uses or for its fundamental importance. A chapter describes the exhaust procedure in which is emphasised the care which has to be taken in the freeing of the container walls and electrodes from gas. Prof Newman's short account of making glass to metal joints shows that he is unaware of the ease with which such seals are now carried out on a technical scale even up to a diameter of several inches. As a whole the book is an excellent one and will be welcomed by all who are interested in the subject. R. L. E. R.

The Indo-Sumerian Seals Deciphered: discovering Sumerians of Indus Valley as Phœnicians, Barats, Goths and Famous Vedic Aryans, 3100-2300 B.C.
By Dr L. A. Waddell. Pp. xxiv+146. (London: Luzac and Co., 1925.) 10s. net.

COL. WADDELL, the well-known authority on Tibet, has stepped in where archæologists, as yet, fear to tread. He has produced an interpretation of the remarkable seals which were found, with other relics suggesting an affinity with ancient Sumeria, at Mohenjo Daro and Harappa in the Indus Valley, and illustrated and described by Sir John Marshall, Director of the Archæological Survey of India, in the *Illustrated London News* in September of last year. "Within a day or two of receiving the photographs," says Col. Waddell, "I was able . . . to decipher and read the greater part of the inscriptions on the seals."

According to Col. Waddell's interpretation, the seals provide a record of the rulers of a Sumerian colony in the Valley of the Indus of the third millennium B.C. His system of interpretation is revolutionary and entails a complete revision of the results obtained hitherto in dealing with Mesopotamian records. Detailed discussion of his conclusions would therefore be unprofitable without previous acceptance of the argument by which he justifies his method of attacking the problem. This is based upon theories which have been expounded in part, though not entirely, in a previous publication in which an attempt was made to prove, not only that the Phœnicians were the ancestors of the Britons, Scots and Anglo-Saxons, but also that they were Aryans and the ruling Aryan class of India. The kings of the early Aryan dynasties of India, it was maintained further, had never been in India, but were kings in western Asia and were to be identified with the kings of early Mesopotamia—Sumeria and

Akkad Col. Waddell regards the seals as confirming his theories; but it must be obvious that an interpretation which is entirely individual depends upon, rather than confirms, a theory which still lacks conclusive demonstration. For it must be stated that Col. Waddell's views, particularly in so far as his etymological arguments are involved, have not met with the acceptance of those most competent to judge. Until the author has brought forward more cogent arguments for the identification of the kings of the Indian lists with those of Mesopotamia—a subject with which it is understood he proposes to deal in a later work—the riddle of the seals remains unsolved.

Aufgaben und Lehrsätze aus der Analysis. Von Prof. G. Pólya und G. Szego. (Die Grundlehren der mathematischen Wissenschaften in Einzeldarstellungen, Band 19 und 20) Erster Band: Reihen, Integralrechnung, Funktionentheorie. Pp. xvi+338. 15 gold marks. Zweiter Band: Funktionentheorie, Nullstellen, Polynome, Determinanten, Zahlentheorie. Pp. x+407. 18 gold marks. (Berlin: Julius Springer, 1925)

Most French and German mathematical text-books differ from the English books in one important particular: they contain no examples for solution. The working of problems and examples has long been one of the features of English mathematical teaching. All able mathematical students of a generation ago were expected to gain practice in manipulation by solving hard problems. Wolstenholme's problem book reflects the tendency of the period in which it was compiled, a large proportion of its examples being somewhat artificial in character despite the elegant solutions they admit. Now the tendency is to avoid problems involving hard manipulation, it being considered that familiarity with mathematical subjects can be gained by working easy examples constructed to test a student's knowledge of fundamental principles. The new Wolstenholme still remains to be written.

Meanwhile, Prof. Pólya and Herr Szego, in the two volumes before us, have brought together some 1500 problems dealing with the subjects of analysis above noted. A large proportion of the questions can be solved at sight; others involve results taken from research papers in the journals, and few readers will see through these without referring to the solutions. The books will be of great value to honours students of pure mathematics in universities, and a lecturer will find innumerable suggestions for examples to set before his classes. W. E. H. B.

Air Ministry: Meteorological Office. British Meteorological and Magnetic Year Book, 1917. Part 5: *Réseau Mondial, 1917.* Monthly and Annual Summaries of Pressure, Temperature, and Precipitation at Land Stations, generally Two for each Ten-degree Square of Latitude and Longitude (M.O., No. 229 g, Tables) Pp. xiv+116 (London: H.M. Stationery Office, 1925.) 22s. 6d. net.

THIS publication deals with the weather results for the whole globe, and similar results are now available for the eight years 1910-1917. The means are compared with normals and the differences are given for each element for each station. The statistics for each additional year add much of real scientific value in the

direction of preparing for long-period forecasts. It is now possible to see how excess or defect from the normal in one part of the world influences weather experienced in another part. It is a fairly simple study to ascertain whether the pressure of the air at the earth's surface is practically uniform at different times over the whole globe. All the information refers to land stations, no data over the sea being as yet obtainable. The number of stations utilised is 458, which is an increase of 18 since the previous issue for the year 1916.

The highest mean shade temperature for the year 1917 was 87° F. at Sokoto and 86° F. at Berbera, Somaliland; the lowest mean 6° F. at Verkhoiansk. The absolutely highest shade temperature recorded is 123° F. at Baghdad on July 21 and at Jacobabad on June 11; the absolute lowest temperature was -81° F. at Verkhoiansk on January 19. The heaviest total rainfall for 1917 was 9850 mm (388 in.) at Cherrapunji, the least 1 mm. at Iquique.

Schlich's Manual of Forestry By Sir William Schlich. Vol 3: *Forest Management, including Mensuration and Valuation.* Fifth edition, revised, and the greater part rewritten. Pp. viii+383. (London: Bradbury, Agnew and Co., Ltd., 1925) 20s. net.

IN this fifth edition of vol. 3 of Schlich's "Manual" the number of pages is slightly less than in its predecessor. Room has been found, however, for a considerable mass of new material, and for several new figures, by judicious compression and elimination, so that the work is brought up-to-date with the examination of new ideas and practice in forestry. Those who peruse the several publications devoted to the science of forestry in England and in India are aware that the author has kept in touch with the latest developments, and here he brings to bear his keen faculty for criticism and for the correct appreciation of modern tendencies.

All the features and main divisions of the previous edition are retained and improved. Among the added subjects the British Forestry Commissioner's method of determining the volume of whole woods is described and criticised. Sir William's own graph for indicating the mean forest per cent., first published by him in his pamphlet "Forestry in the United Kingdom" in 1904, is now included, as well as a reference to Mr W. S. Hiley's indicator graph, and among the modifications of the compartment system, Dr. Eberhard's ingenious system of wedge fellings is discussed. The controversy on the question of the rate and kind of interest to be adopted in forestry has led to the inclusion of a paragraph explaining why the application of compound interest in forest finance is insisted upon.

The volume is produced in the now familiar, neat, and handy form of the former editions, and should find place on the reference shelves of every scientific forester. C. E. C. F.

A Survey of Physics: a Collection of Lectures and Essays. By Max Planck. Translated by R. Jones and D. H. Williams. Pp. vii+184. (London: Methuen and Co., Ltd., 1925.) 6s. net.

Messrs. Methuen are doing a real service to science by their publication of translations of foreign scientific works, but they are not always fortunate in their choice of books for translation. It might have been thought

in a book with so attractive a title and by such an eminent scientific worker they had a real certainty. The book itself, however, somewhat disappointed our, perhaps unduly great, expectations. It is a collection of lectures and addresses, delivered on different occasions and at different times, mainly on the thesis that physics has now reached the stage when the attempt to form a mechanical picture of natural processes, which has engrossed the attention of the great physicists of the past, should be definitely abandoned, and we should satisfy our souls with the subtleties of thermodynamics and the search for an all-embracing formula. The author develops his thesis forcibly and ingeniously though, necessarily from the structure of the book, with some repetition, and the book should prove attractive to those interested in the philosophy of science. To the physicist the most interesting chapter is that in which the author sketches the road by which he arrived at the quantum theory. The translators have not always been happy in their rendering of the original. We, at least, had some little difficulty in recognising in "Thales von Milet" our old friend Thales of Miletus.

Joule and the Study of Energy. By Dr. Alex. Wood. (Classics of Scientific Method) Pp. viii+88+8 plates. (London: G. Bell and Sons, Ltd., 1925.) 1s. 6d. net.

THIS excellent little volume could be read not only with profit but also with pleasure by all students of physics from the school-boy stage upward. There is no better way of appreciating the meaning and value of a scientific principle than a study of the ways in which it was evolved, and no better way of gaining a real understanding of scientific method than a study of the work of one of the great pioneers of science. In something under ninety pages, Dr. Wood succeeds in giving a clear and adequate outline of the gradual growth of the conception of energy, and a lucid account of the work of Joule on the mechanical equivalent of heat, illustrated by ample quotations from Joule's papers. At the same time, he finds room for those humanising touches of anecdote and biography which give life and colour to a work of this kind, and the numerous well-chosen illustrations add still further to the interest.

Dr. Wood has a high reputation as a lecturer, and he writes as charmingly as he speaks. Students of physics should certainly read and enjoy the book, but so clear is the exposition that those who, without being students of physics, are interested in scientific thought and method, could read it, we believe, with almost equal pleasure and interest. The editor of the series is to be congratulated on having persuaded Dr. Wood to write this book (we wish he had allowed him to write the general introduction also), and the publishers on producing it in such an attractive form and at so reasonable a price.

Smoke: a Study of Town Air. By Prof. Julius B. Cohen and Dr. Arthur G. Ruston. New enlarged edition. Pp. xii+108+15 plates. (London: Edward Arnold and Co., 1925.) 8s. 6d. net

THE second edition of Prof. Cohen's and Dr. Ruston's book on "Smoke" is modelled closely upon the first. It has, however, some important additions on the effect of smoke on vegetation, and a new section has

been added—"The Plant as an Index of Smoke Pollution." There is much useful information on the nature, quantity, and effect of soot, based mainly upon Prof. Cohen's own observations made in Leeds and its environs some years ago.

The chapter on "Town Fog" can scarcely be taken as setting forth the latest knowledge on the subject. For example, in describing the initial stages of condensation to form particles of mist or fog, p. 66, the vital distinction between the influence of ordinary dust and of hygroscopic salts is neglected, and ordinary dust is credited with an effect on condensation which it does not possess. Similarly, Aitken's "dust" counter is now known to take cognisance of hygroscopic nuclei only, neglecting ordinary dust. Yet this fact is not brought out when it is compared with the Owens' dust counter; the latter is incorrectly described as a modification of Aitken's, although based on a different principle and counting different particles. Again, the conception of a town fog as formed by condensation on "every little floating particle of dust" is not in accordance with the present state of our knowledge.

There is a little obscurity in the phraseology in plan (p. 27), but, on the whole, the book is a welcome contribution to the study of the air of our cities, the need for purifying which is becoming more apparent as such investigations lay bare the far-reaching ramifications of the smoke evil.

The Ao Naga Tribe of Assam: a Study in Ethnology and Sociology. By Prof. William Carlson Smith. (Published by direction of the Government of Assam.) Pp. xxvii+244+8 plates. (London: Macmillan and Co., Ltd., 1925.) 21s. net.

THE Aos, the people studied in this latest addition to the excellent series of monographs published by the Government of Assam, occupy the country lying between the Lhota and Sema Nagas on the south, and the various Naga tribes, collectively known by the Aos as "Miri," in what is mainly independent territory on the north. The Aos are composed of two racial groups, the Mongsen and the Chongli, which Mr. J. H. Hutton in his interesting introductory analysis suggests may have fused comparatively recently, the Mongsen representing a pre-Ao population. The author modestly does not claim for his book that it is any more than an introduction to the study of the people. He has covered a wide field in his account of the culture, social organisation, and religion and magical beliefs of the people, but not in that intensive manner which we have become accustomed to look for in this series. What is, perhaps, the most valuable part of the book, especially from the practical point of view of the future of the people, is the final chapter recording the changes in their culture which have been brought about by contact with outside, and especially European, influences. It is both a guide and a warning.

Nutrition de la plante. 4: Cycle de l'azote. Par Marin Molliard. (Encyclopédie scientifique: Bibliothèque de Physiologie et de Pathologie végétales.) Pp. xv+319. (Paris: Gaston Doin, 1925.) 15 francs

A SUBJECT which has attracted the attention of botanist, chemist, and bacteriologist alike is bound to be unwieldy and its literature difficult to survey in a book of three hundred pages. Especially is this the case

when, being part of a scientific encyclopædia, it must presumably be intelligible to those whose general scientific knowledge is only limited. From this point of view, the book is well written, and the author, while necessarily introducing a good deal of text-book matter—as in Chap. i., which deals largely with tests and properties of various nitrogen containing compounds—has yet found space enough to make reference to more than two hundred original papers. These have been well surveyed, and, in most cases, actual experimental numbers are given. The various stages of the cycle are worked out somewhat on monograph lines in Chaps. ii-v under the self-explanatory headings of nutrition, digestion, and transformation. The sixth and last chapter is devoted to the *bêles noires*, or those nitrogen containing bodies which do not find a definite place in the cycle. The conflicting data and opinions of various authors are given, and the reader advisedly left to form his own. A complete bibliography concludes a very readable and useful book. E. R.

The Lilies of Eastern Asia: a Monograph. By Ernest H. Wilson. Pp. xiv+110+17 plates. (London: Dulau and Co., Ltd., 1925.) 25s. net.

It is not often that a writer on plants has the advantage of having had experience of seeing them in their native habitats, of cultivating them, and of studying them from herbarium material. Mr. Wilson is fortunate in having combined these, and shows in his introduction what good use he has made of his opportunities, so as to arrive at an estimate of the value of the various characters for taxonomic purposes. He has made three journeys through those parts of eastern Asia which may be regarded as the headquarters of lilies, and has also studied the material preserved in the chief herbaria of the world. The result has been the production of a volume containing detailed descriptions of the species and varieties, references to literature and synonymy, indication of habitat and notes on their cultivation, together with seventeen plates, of which several are reproductions of photographs taken by the author, of the plants in their native habitats. The book will be of great assistance to students of lilies, and gives references to the scattered literature which has accumulated since the publication in 1880 of Elwes' "Monograph of the Genus *Lilium*."

C. H. W.

Wireless Valve Transmitters: the Design and Operation of small Power Apparatus. By W. James. Pp. viii+271+8 plates. (London: Iliffe and Sons, Ltd., 1924.) 9s. net.

THE aim of the author is to deal in turn with the various parts of a complete radio transmitting equipment so as to enable the amateur to set up and operate his own transmitter. A great deal of interesting and instructive work can be carried out by a "non-radiating" aerial, and certainly this type should be used by the beginner. The circuit arrangements described are either standard practice or of proved practical utility. The author's diagrams make his descriptions easy to follow. Those whose experiments are carried out mainly by trial and error will do well to read this book. Amateurs have recently had many successes to their

credit, and they deserve every encouragement. Rigorous mathematicians would not allow some of the proofs given in the book. For example it is stated (p. 7) that the skin effect is greater the larger the cross-section (S), the higher the frequency (f), and the better the permeability (μ). It is less for conductors with a high specific resistance (ρ). "Thus" the skin effect is proportional to $S\mu f/\rho$. It is conceivable that some readers might think that this was a proof.

Choosing your Life Work. By William Rosengarten. Second edition. Pp. xxii+323. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1924.) 12s. 6d. net.

THIS book sets out with the aim of helping a young boy to choose a career. According to the author, psychological tests are so new and uncertain that for practical purposes they are almost as untrustworthy as phrenology and physiognomy. Therefore the youthful aspirant for a career is recommended to analyse himself according to the *questionnaire* appended and then to turn to the various occupations and select according to his fitness. A chapter is devoted to each of the common occupations, and the requirements, emoluments, and drawbacks to each are described. It is distressing to learn that the telegraphist, although he fulfils a very important function, is unlikely to win high financial reward. As a handbook to various trades, the book may be useful; its style is verbose and the information it gives would not have been impaired by judicious compression. The blend of moral "uplift" and commercialism is not attractive to the English reader.

The Dust Hazard in Industry. By Dr. William E. Gibbs (Chemical Engineering Library: Second Series) Pp. 168. (London: Ernest Benn, Ltd., 1925.) 6s. net.

THE subject dealt with in this book is one of great importance. Industrial dust is frequently a source of danger, either to health, or to life and property by causing explosions. Although much valuable information is available, the publications are scattered, and the author has performed a useful service in collecting and arranging the material in a readable form. Particular attention is paid to dust explosions, on which much useful information has been obtained at the Home Office Experimental Station at Eskmeals. American results, of great value, have also been fully considered, and the book is authoritative. Some of the information will be of interest to medical men as well as to chemical engineers. The name of the chief authority on explosions, Prof. H. B. Dixon, does not appear in the book, although many of his results are quoted.

Mechanical Mixing Machinery. By Leonard Carpenter. (Chemical Engineering Library, Second Series.) Pp. 138. (London: Ernest Benn, Ltd., 1925.) 6s. net.

ALTHOUGH this book deals with dry mixing, it overlaps in parts the volume on the same subject by Mr. Seymour in the same series. It is not altogether clear why the publishers should have thought it necessary to have had two volumes dealing with the same subject in the same series, but the two books will no doubt appeal to different classes of readers. The treatment is practical, and the book is well illustrated.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Ionisation Potential of Ionised Manganese.

IN his paper on the manganese spectrum (Phil. Trans. Roy. Soc., vol. 223 A, p. 127) Catalán gives some triplets and multiplets of the spectrum Mn II, and suggests identifications of some of them. I have recently made an attempt to estimate terms from some of these lines; two independent methods agree within the estimated limits of error, and it seems that it is possible thereby to estimate the ionisation potential with an error probably less than half a volt.

Catalán (*loc. cit.*) suggests that the enhanced triplet $\lambda\lambda$ 2576, 2594, 2606, and multiplet consisting of three triplets near $\lambda\lambda$ 2428, 2438, 2453 are the first principal and first diffuse triplets of Mn II. Back (*Zeit. f. Phys.*, vol. 15, pp. 238-40) has confirmed the first of these identifications by the Zeeman effect, and has shown that the terms belong to a septet system similar to the Cr I septets (for which see Gieseler and Grotian, *Zeit. f. Phys.*, vol. 22, p. 228), and he agrees with Catalán's identification of the diffuse multiplet.

Further, Catalán states that the lines $\lambda\lambda$ 2576, 2594, 2606 forming the first principal triplet are the most persistent of the enhanced lines of Mn, so they are probably the "ultimate lines" in Russell's sense (*Astrophys. Journ.*, vol. 61, p. 223), and if so, the septet $1s$ term corresponds to the normal state of the atom.

Now Hund (*Zeit. f. Phys.*, in press) has shown reason to believe that the distribution of electrons in the Cr and Mn⁺ atoms in their normal states is the same (5 electrons in $3s$ orbits and 1 in a $4s$ orbit, the inner n_k sub-groups being complete; this is the only case in the iron group in which the normal state of a neutral atom has the same distribution of electrons as the normal state of the ionised atom in the previous place in the periodic table), so the $1s$ terms of the Cr I and Mn II septets are really corresponding terms. Also for Cr I the zero of term value corresponds to the ionisation of the atom by removal of the $4s$ orbit, and if we take a corresponding zero for Mn II it seems likely that quantitative relations between the septet terms of the two spectra can validly be applied.

From the principal triplet alone it is possible to estimate term values in two ways. The quantum defect q for the n_k term, wave number ν , of an atom core charge C being defined by $\nu/R = C^2/(n - q)^2$ as usual, the two estimates are as follows:

(1) For Cr I septets, the s terms belong to a sequence of the Rydberg type, so they can be associated with different orbits of a single series electron, and the concept of a quantum defect is significant; and the first p term (Gieseler and Grotian's 4_2) looks like the first member of a Rydberg sequence. The difference of quantum defect between the first s term and the smallest member of the first p term is 0.46; judging from the behaviour of the similar difference in other spectra, it seems probable that its value for Mn II septets will lie between the limits 0.35 ± 0.02 . Using the first principal triplet above mentioned, this gives $1s(4_1) = 119,000 \pm 4000$.

(2) The triplet separation for the p term of Cr I fits the Landé formula (see *Zeit. f. Phys.*, vol. 25, p. 48) fairly well, so it may be expected that the relation between the separations for corresponding terms of Cr I and Mn II will be given by this formula. The

best way of applying it is through Δq , the difference of quantum defect q between the extreme members of a multiple term. The value of Δq for the 4_2 term of Cr I septets is 0.00584; for the corresponding term of Mn II it would be expected to be about 0.0061. The value of $\Delta\nu$ is known from the separation of the first principal triplet, so the value of the term can be calculated. It leads to a value $1s = 116,000$, the limits of error being estimated at ± 5000 .

The agreement of the two independent estimates, one from the position of a line of the triplet and the other from triplet separations, is most satisfactory; it seems likely that the $1s$ term of the Mn II septet system lies within the limits $118,000 \pm 3000$. The ionisation potential corresponding to the removal of the 4_1 electron is then 14.5 ± 0.4 volts.

It seems possible that similar methods may be of use in providing approximate values of terms of other spectra of ionised atoms, of which only a few lines are known, if suitable lines can be identified.

The Future of the British Patent Office.

PATENT Law is a means to an end, and until the nature of the consideration which the patentee is to bring in in return for his monopoly has been clearly ascertained, it is idle to attempt to lay down what should or should not be the appropriate practice at the Patent Office. Now the object of British Patent Law has varied materially during the last three hundred years.

Coke, for example, is the chief authority for the construction of the Statute of Monopolies and this is his commentary: "The reason wherefore such a privilege is good in law, is because the inventor bringeth to and for the Commonwealth a new manufacture by his invention, cost and charges, and therefore it is reason that he should have a privilege for his reward" (Coke, 3 Inst. 181). Under the Stuart dynasty, the jurisdiction of letters patent was reserved to the Privy Council. This body administered the Statute of James in the sense of Coke's dictum. It insisted that the patentee should make good at the earliest opportunity and was always ready to revoke an unused patent in favour of a second applicant with better credentials; the latter became "the true and first inventor" under the Statute. About 1750, however, its jurisdiction was allowed to lapse, and patentees henceforward were compelled to seek their remedy in the Courts of Law. The latter, being without recent precedents to guide them, interpreted the contract in the letters patent in the light of the specification clause, and in 1778 it became established law that the patent specification was the price of the monopoly.

This doctrine held the field until 1883, when the needle of patent law again began to show signs of instability. The Patents Act of that year contained certain inoperative compulsory licensing clauses, which were afterwards strengthened, but in 1919 the needle once more veered round with a swing to the Statute of Monopolies—the Act of 1919 laying down that "patents for new inventions are granted not only to encourage invention but to secure that new inventions shall, as far as possible, be worked on a commercial scale in the United Kingdom without undue delay, and further providing that a patent shall not be invalidated by the prior sale of the inventors' product if a patent has been applied for within six months of such sale."

Hence there are two basic principles of patent law, (a) that patents are granted in consideration of the disclosure of inventions; (b) that they are granted for the institution of new industries.

Although both principles may fitly be recognised in a given system of patent law, they cannot be regarded as coequal. For the type of administration appropriate to (a) not only differs from, but also is even antagonistic to, that which would naturally be evolved under (b). Under (a) there must be a highly elaborated machinery for the investigation of novelty, with the result that patents will be granted with relatively narrow claims, and that the capitalist be able to buy inventions cheaply, for patents will possess little restraining power. An official search, no doubt, gives additional security, but the commercially valuable factor in a monopoly is its restraining power. Hence, as a general rule, when security is at its highest the other factor will be "little, or none at all."

Trustworthy evidence of the commercial value of patents is not readily obtainable—for it is against the interest of patent officials, agents and owners alike publicly to depreciate their own services or properties. The following communication, however, was sent to the present writer in 1923 from a well-known scientific writer in Washington. He writes: "I have been wondering for some time whether the world's patent offices are not about to break down under their own weight. Simple arithmetic shows that the possible permutations and combinations of known principles and kinds of matter are so numerous that their task is hopeless unless the definition of invention or originality is radically changed. The U.S. Patent Office is already in a badly demoralised state and far behind with its applications, and its patents have for some years been recognised as worthless in themselves, being essentially only tickets of admission to the courts of law." Corroborative evidence on this point will be found in my letter to NATURE, Nov. 11, 1922, p. 633. These are inside views of the effect of a universal search upon the selling value of patents.

The writer of the articles in NATURE of July 25 and August 1 proposes a search through the 1759 periodicals taken in the Patent Office Library. But what about the 24,028 registered in the recently published "World List of Scientific Periodicals"? His search is to be limited to suit the convenience and capacities of the examining staff. Section 41 (1) of the Patents and Designs Act 1907 established the principle that "what we don't know isn't knowledge" in order to round off the official 50-year search (see my letter as above). When I pointed this clause out to a legal authority, he said it was "damned nonsense"—but it is proposed in the articles referred to above to extend the principle.

The remedy is obvious. An administrative search for novelty has long been an economic absurdity. The direction in which reform should be sought, if the object of our patent law is to stimulate the growth of British industries, is in the relief of the patentee from the unduly high legal standard of novelty. Sir John Dewrance in his presidential address before the Institution of Mechanical Engineers in 1923 supports this contention. He writes: "It has always seemed to me to be unfair that documents should be evidence of anticipation: evidence should be of prior use." This relief can, of course, be granted to the patentee only upon proof of commercial working.

Hence official search for novelty should be restricted to secure that concurrent British patents are not granted with overlapping claims. With a simplified procedure and broader claims, which can be substantiated so soon as the patented process has been

reduced to practice, capital will once more flow into native industries.

Underlying the case presented in NATURE is the thesis that the public requires to be protected against the inventor. My case is that the inventor should be wooed and if possible won to come over and help us, and for this purpose I would make the law clear and consistent and the official practice cheap and expeditious.

E. WYNDHAM HULME

A Radio Method of Estimating the Height of the Conducting Layer.

IN a recent note we have outlined a method of estimating the height of the conducting layer by means of radio waves (M. A. Tuve and G. Breit, *Terr. Mag.*, vol. 30 (1925), pp. 15-16). Through the co-operation of the U.S. Naval Research Laboratory, Bellevue, Anacostia, D.C., we have obtained definite indications of reflections such as would take place from the layer and some estimates of its height. The method used consists in sending out interrupted high frequency wave-trains and observing the wave-form of the received signal. Each wave-train received manifests itself as a temporary rise in the detector current of the receiving set. One particular wave-train at the transmitter gives rise to two received wave-trains at the receiver if a single reflection takes place. One of these trains travels over the ground and the other by way of the layer. Thus the detector current is forced to rise at two different times by the same wave-train from the transmitter and an oscillogram of the detector current shows two humps generally of unequal size.

The transmitter was operated with a 500-cycle plate current supply so that a wave-train of 71.3 metres wave-length was emitted during a part of each positive half of the cycle. A succession of single humps is thus emitted. (We have made sure of this by observing the wave form at the same time at the transmitting and the receiving stations.) The receiving station was located 7 miles away from the transmitter in a general direction north, the Potomac River and the City of Washington being between the two stations. We have observed the received wave-form visually and photographically. Double and triple humps were observed on some days, though practically single humps were observed on others. Marked variations in the relative position and amplitude of the humps were observed during 10-minute observation periods. The retardation of the secondary humps with respect to the primary is of the order of 1/1700 second, which corresponds to a retardation over a length of roughly 110 miles and a distance of the layer of the order of 50 miles. Other humps correspond to 100 miles. The origin of triple humps is not clear. The possibilities of a wavy surface in the layer and successive reflections suggest themselves.

Experiments on other wave-lengths with different receivers and transmitters and in different locations seem valuable. We are hoping that such experiments will be performed by others as well as ourselves. Some experiments at 600 metres were performed in co-operation with the Radio Corporation of America, the distances between the two stations being about 150 and 100 miles. No definite indication of the presence of the layer was found in these cases.

Science and Intellectual Freedom.

IN the issue of NATURE for July 18, p. 103, it is stated "Our sole object in taking up the subject of the prohibition of the teaching of evolution in certain States of the United States, and in inviting opinions upon this action from a number of leading authorities, has been to afford support to our colleagues fighting for scientific truth and progress against dogma and stagnation. We trust that the additional messages subjoined will give them the strength and courage they need to secure for them the position of intellectual freedom established in Great Britain many years ago, and existing unchallenged to-day."

It is possible to appreciate the good intentions of this patronage without admitting its need. Not intending to bite the hand that feeds us, I still venture to express a doubt as to whether the strength and courage of American men of science in their efforts to attain the intellectual freedom established in Great Britain will be greatly forwarded by the series of little articles published in NATURE and by the editorial comments.

Tennessee is the only State concerned, and it does not forbid the teaching of evolution, but only the teaching in tax-supported institutions of the derivation of man from a lower order of animals. The law is unfortunate, and is opposed by general public sentiment as well as by men of science. It should, however, be remembered that Tennessee also forbids the reading of the Bible in its public schools, it does not expect them to teach that the evolution of man is not true. The control of teaching by legislation is unwise, but no sensible teacher would want to lead children to question the religious convictions of their parents. Intellectual freedom is also interfered with when a premier prescribes that the children of a nation must study Latin, thus leaving no time for the study of science.

There is a larger proportion of "Fundamentalists" in every European nation than in the United States, and also a larger proportion of educated people who profess, without believing, the thirty-nine articles and other inherited creeds. Sir Joseph Larmor, the distinguished man of science who represented the University of Cambridge in Parliament, made it one of his chief pleas when he was first a candidate that he would support the maintenance of the control of the Church of England over tax-supported schools. It is not surprising if a majority of the rural population of Tennessee hold the creed that Mr Gladstone defended and that Lord Balfour exploits in more sophisticated fashion. They would scarcely follow the vagaries of Sir Oliver Lodge. The only scientific man here who manifests an interest in such things was sent to us from the University of Oxford. But perhaps it is undesirable to make international comparisons.

J. McKEEN CATTELL.

New York, July 30.

On the Spectra of Neon and Argon in the Extreme Ultra-violet.

At the April meeting of the American Physical Society (see *Physical Review*, 25, 886, 1925) we reported the existence of a very strong pair of lines in the spectrum of neon at $\lambda\lambda$ 743.78 and 735.95, together with some ten other lines, all combinations with a fundamental $1p$ term in this spectrum. We are glad to see that G. Hertz (*Die Naturwissenschaften*, May 29) has independently found the same strong pair, and that their position agrees satisfactorily with our measures and with that obtained by him from resonance potential observations.

It is perhaps worth while to note that the spectrum of argon contains a similar pair, at $\lambda\lambda$ 1048.28 and 1006.73 (± 0.2), together with a number of other lines of shorter wave-length, which are probably components of a like pattern. The strong pair fits exactly the resonance potential, 11.5 volts, found by Hertz. Another observed pair corresponds to its value of 14.0 volts. His third resonance potential, 13.0, seems not to correspond to any emission line, but the presence of unidentified impurity lines in our spectra makes it necessary to take further observations before giving final data.

The complete argon spectrum is probably like that of neon. The strong lines are therefore combinations of a fundamental $1p$ term with terms $1s_2$ and $1s_1$. The latter combine with other terms, as yet unknown, to produce several lines which are listed in tables of constant wave-number differences (cf. Kayser, "Handbuch," 7, p. 26, where two of the columns refer to such combinations). More observations on the spectrum of argon are, however, needed before the structure of the spectrum can be worked out.

In neon a curious fact has been noted. The line at λ 735 is normally stronger than that at λ 743, it is in fact the strongest line in the whole spectrum. When, however, a small quantity of neon is present as an impurity in helium, the relative intensities of the lines of this pair reverse, λ 735 becoming the weaker of the two. Our observations make it seem unlikely that this could be due to the presence of a sharp-edged absorption band in our helium. One would therefore suppose that collisions between atoms of neon and of helium render the peculiar atomic state yielding the line λ 735 less probable than is the case when the neon is alone. Argon as an impurity in neon shows no such effect.

Harvard University, July 25

Lunar Periodicity in Obelia.

IN Proc. Roy. Soc., vol. 95, 1923, Mr. H. M. Fox directed attention to a number of cases of "Lunar Periodicity in Reproduction" in marine organisms. To these may be added the hydroid *Obelia geniculata*. At first sight the periodicity is masked by the irregular breeding of colonies which are wave-worn or much eaten down by nudibranchs, but if attention is confined to healthy and perfect colonies, the lunar periodicity seems quite definite. During 1924 several colonies on the piers were located and watched, the best result was from a colony on Laminaria on Millport old pier, which was giving off medusæ during the ten-day periods beginning with the third week of the moon in July, August and September, and not at other times. Other colonies gave definite results in two consecutive months, but were then attacked by nudibranchs or lost.

More recently, twelve colonies at Keppel were examined on July 28 (first moon quarter)—none of them had gonothecæ, one colony had minute axillary buds beginning to form gonothecæ, on August 5 (full moon August 4)—of fifteen colonies examined, eight were worn, frayed or eaten, the remaining seven were healthy and ripe, including small colonies of only five or six branches, probably three weeks old.

Miss S. M. Marshall has confirmed these observations by noting occasional abundance of *Obelia* medusæ in the plankton about the third quarter of the moon. Colonies which have been much eaten by nudibranchs may, if abundant food be present,

recover rapidly and reproduce at any time, to which is probably due the fact that this case of lunar periodicity has escaped observation

Magneton Numbers of Iron in some Complex Salts.

DR. L. C. JACKSON's letter in NATURE of June 27, p 981, points out the fact that an iron atom, known definitely to be ferrous, can have at least four distinct magnetic moments, namely, 26, 26.5, 27, and 27.5 when expressed in the magneton of Weiss. The purpose of this note is to present preliminary data tending to show that the magneton numbers for ferrous iron are not limited to 26-27.5, but can be 0 and 10 as well. Likewise, a ferric iron atom can have a magnetic moment corresponding to 0 and 10 magnetons in addition to the 29 magnetons usually obtained from measurements on simple paramagnetic salts. An example is included of an iron compound, the carbonyl, in which the iron certainly plays the part of a diamagnetic element

The data appear in the table below. The mass sus-

making use of Pascal's measurements on this salt in a dilute solution (*Ann. Chim. Phys.*, 1909, 16, 531, 8th ser.) Weiss's value, 10.41, becomes 10.2 when revised on account of the newer susceptibility, $k = -7.19 \times 10^{-7}$, assigned to the water used as a standard. 10.2 was therefore adopted as the correct magneton number for potassium ferricyanide, and all of the others were calculated by taking the magneton number to be proportional to the square root of the net susceptibility.

We note at once that the magneton numbers group themselves around ten and, very probably, zero. There is no doubt as to the ferric salts, provided that we accept the value of 10 magnetons for potassium ferricyanide. The fact that the ferrous diamagnetic salts give magneton numbers up to 1.5 may be due to the presence of small amounts of paramagnetic impurities or to uncertainties about the diamagnetic constants used in calculating the net susceptibilities. Both of these factors are important in dealing with diamagnetic substances. According to the table, the last ferrous salt, $\text{Na}_3\text{Fe}(\text{CN})_5\text{OH}_2 + \text{H}_2\text{O}$, does not yield 10 magnetons. 6.5 is the highest value yet observed. The salt is difficult to prepare and becomes more and more paramagnetic on repeated recrystallisation. At first it seemed to approach

ceptibilities for potassium ferricyanide, potassium ferrocyanide, and iron carbonyl are taken from a paper by Oxley (*Proc. Camb. Phil. Soc.*, 1910-12, 16, 102), whose values have been recalculated since the susceptibility, k , of the reference substance, water, is now considered to be -7.19×10^{-7} rather than -7.5×10^{-7} . The other complex salts are formed by the substitution of the radicals NH_3 , NO_2 , etc., for one of the CN groups in either the ferricyanide or the ferrocyanide of sodium. One of them is the well-known sodium nitroprusside. The other seven were prepared by Dr Baudisch of this Institute, who followed, in general, the methods described by Hofmann (*Annalen der Chemie*, 1900, 312, 1).

The net susceptibilities pertaining to the gram atom of iron were obtained by allowing for the diamagnetic moment due to the atoms other than iron. For this purpose use was made of the diamagnetic constants listed by Pascal (*Revue générale des Sciences*, July 15, 1923). Since my measurements were made on the salts in the solid state, the Weiss formula for the magneton number

$$N = \frac{\sqrt{3RTK_i}}{1123.5}$$

is not directly applicable. But Weiss (*Jour. d. Phys.*, 1911, 1, 965, 5th ser.) has already calculated that iron in potassium ferricyanide has 10.41 magnetons by

5 Weiss magnetons, or one of Bohr's, as a limit. Since it passed 5 magnetons its upper limit is now believed to be 10. At any rate the magneton number of the iron in this salt is known to be greater than 6.6.

Still more interesting than this grouping of magneton numbers about zero and ten is the appearance of two inversions. Iron in most of the ferric salts has 10 magnetons, but in at least one ferric salt it has none. Similarly, the ferrous salts usually contain no magnetons, but in one of them we find at least 6.6 and very probably 10. We see then that the magnetic moment of iron is extremely variable, and that it is not uniquely defined by a statement of its valence.

Gerlach (*Ann. der Phys.*, 1925, 76, 163) has recently observed that iron in the vapour state has no magnetic moment. This suggests that its paramagnetic properties in a salt, either solid or dissolved, are due entirely to the distortion of its electron system by the neighbouring atoms with which it is combined, or by the water molecules surrounding the ion. Altogether there seem to be at least seven principal states in which the iron may exist on account of these external forces of a chemical nature. Putting it in another way, there are at least seven main configurations of the electron system known to us as the iron atom. They are ferric iron, giving 0, 10, and 29 magnetons, ferrous iron giving

o, 10, and the group of 26 to 27.5 magnetons; and then there is the iron which is nearly as diamagnetic as Pascal (*Revue générale des Sciences*, July 15, 1923) has found bismuth to be in its compounds.

LARS A. WELO.

Rockefeller Institute for Medical Research,
New York, July 23

MR. WELO's interesting letter directs attention to the fact that the iron atoms in various complex cyanides possess quite different magnetic properties from the iron atoms in simple ferrous or ferric salts. The existence of iron atoms which are either paramagnetic, but have a moment considerably smaller than that found in the simple salts, or even diamagnetic (zero magnetic moment) finds a parallel in the observation of Pascal that oxygen may function in organic compounds as a paramagnetic element with the "usual" moment, as paramagnetic with a lesser moment and also as diamagnetic.

The susceptibilities of a large number of complex co-ordination compounds of cobalt and nickel are known. It would be of considerable interest to carry out similar calculations to Mr. Welo's with these data also. Cobalt and nickel atoms with zero magnetic moment may be expected, but the interesting point would be the determination whether these elements exist in modifications analogous to Mr. Welo's iron with 10 magnetons.

It may be of interest to mention the non-magnetic films of nickel which have recently been described. Their existence has been ascribed elsewhere to a rearrangement in the electron configuration similar to that suggested by me in the letter referred to by Mr. Welo. By this rearrangement the electron configuration of the nickel atom becomes completely symmetrical and hence the atom possesses no magnetic moment.

A further study of data such as are given by Mr. Welo and those derived from the simple salts of the magnetic elements is likely to be of considerable interest in giving some evidence of the deformations or rearrangements of the electron orbits of an atom in a solid compound. The magnetic properties of the free undeformed atom may be inferred from spectroscopic data.

Two further points may be mentioned in connexion with Mr. Welo's letter. First, his method of calculation of the magneton numbers implicitly assumes that the various substances obey Curie's law $KT=C$. In general, however, paramagnetic substances obey the more general law, $K(T+\Delta)=C$, so that a single measurement at one temperature is not sufficient for the determination of the Curie constant C , from which the magneton numbers are calculated according to Weiss. Mr. Welo's numbers may, therefore, need a correction on this account. Further, it is scarcely permissible to calculate the Bohr magneton numbers merely by dividing the corresponding Weiss numbers by 5 since, though the Bohr magneton is essentially a quantum unit, no account is then taken of the spatial quantisation factor.

Secondly, it seems that there is a slight misunderstanding of the purpose of my letter already referred to. It is perfectly reasonable to expect that iron atoms in quite different modes of combination should possess different magnetic properties, but in the letter attention was directed to the fact that iron atoms in ferrous compounds may exist in different magnetic states in one and the same compound. Thus the four values of the magneton number there mentioned were obtained from observations on ferrous ammonium sulphate.

L. C. JACKSON.

The Band Spectra associated with Carbon.

HAVING read with great interest the two communications by Prof. Raymond T. Birge, published in *NATURE* of August 1, p. 170, and August 8, p. 207, I should like to direct attention to the fact that I gave in 1924 the description and wave-lengths of the band spectrum described a year later by Dr. R. C. Johnson as "A New Band System" in *Proc. Roy. Soc. A*, 108, 349, June 1925, and called "the new Johnson group" by Prof. Birge (*NATURE*, August 8, p. 207).

My first publication concerning these new bands appeared in *Comptes rendus*, 178, May 5, 1924, p. 1525, under the heading "Sur les spectres de la décharge thermionique dans l'oxyde de carbone. Nouveau spectre de bandes" (italics mine here). It was also published with a photographic reproduction of the bands in *L'Astronomie*, 38, Nov. 1924, 444, Fig. 236.

The thermoelectronic bulb filled with pure carbon monoxide at a pressure of about half a millimetre gives with intensity only the three double-headed bands at λ 4236, 3978, 3730, while the helium mixture of Dr. Johnson gives three additional bands. So far as I can judge with such a limited number of bands, it appears that the distribution of the intensities seems a high-temperature distribution with thermoelectronic bombardment, while it would be a low-temperature distribution in a helium mixture. Prof. Birge has rightly made the same remark for the comet-tail bands (*NATURE*, August 1, p. 171).

Since the publication of my above-mentioned papers, I have obtained the three bands with a great dispersion, and I will give later the analysis of their fine structure.

F. BALDET.

Observatoire de Meudon, August 12.

The Transport of Organic Foodstuffs in Plants.

FROM the ringing experiments of early times, it has reasonably been inferred that foodstuffs are translocated downwards by the phloem. But to complete the evidence it would be necessary to prove directly that the tissues external to the wood can translocate foodstuffs by themselves. Adequate experimental evidence for this has never been produced, and recently it has been maintained that downwards as well as upwards the foodstuffs must be translocated by the wood. (Dixon, H. H., and Ball, N. G., *NATURE*, February 23, 1922, vol. 109, p. 236.)

Evidence for translocation by the rind I have, however, now been able to obtain by rooting shoots of *Salix fragilis* in tap-water, and peeling off from below upwards strips of rind from 4 to 8 cm long, each carrying a root. The strips remained connected with the shoots above. The roots on these strips grew at rates up to a centimetre a day, and nearly as fast as similar roots on intact parts of the same shoots. They continued to grow indefinitely. The foodstuffs for their growth must have been translocated from the shoot, for roots on short, completely isolated strips of rind grew only for a few millimetres and then stopped, showing that the local supply was insufficient. Since new wood did not begin to be regenerated for from four to eight days, the foodstuffs must have been translocated by the rind alone.

It should be mentioned that before the roots on the strips of rind could be got to grow, it was found necessary either to prevent the water surrounding the roots from touching the inner surfaces of the strips, or to keep this water sterile with one part in 120,000 of thymol.

It is hoped to continue the experiments next spring.

The New Ideas in Meteorology.¹

By Dr. G. C. SIMPSON, F.R.S.

THE first quarter of the twentieth century will always be remarkable for the great advances made in science. In our own particular branch the advance has probably been the most startling and has appealed very strongly to the popular imagination. In mathematics we have had a little-known and even less-understood branch of pure mathematics applied to physical problems with results which have revolutionised our whole conception of the universe in which we live. In astronomy we have had described to us an evolution of the heavenly bodies as real and as dominating as the evolution which the previous century revealed in the animal kingdom. In physics the progress made has been most remarkable. At the beginning of the century, it is true, we had been introduced to the electron, to Röntgen rays, and to radio-activity; Planck was also writing on the laws of radiation; but no one realised the powerful tools which these phenomena were going to put into the hands of physicists. These tools have, however, been used, and not least by our own countrymen, to dig deep into Nature's secrets, even into the atom itself, so that now we are able to visualise the component parts of an atom, which itself is a structure far removed from our powers of perception.

Meteorology, although a child of applied mathematics and physics, has scarcely been touched by the epoch-making discoveries in the house of its parents. The quantum has found no place in our theories of the mechanism of the atmosphere, a knowledge of the structure of the atom has not helped us to understand the physics of the air as we deal with it in meteorology; the relationship between mass and charge, the invariability of the velocity of light, four-dimensional space and all the other new conceptions which have been responsible for the advance of physics, have been of no help to meteorologists in their especial branch of science.

The whole attention of physicists has been so dominated by these new ideas, and the vistas of unexplored country which they have opened out are so vast, that it is no wonder that physicists have had no interest in a domain in which their new tools could not be employed. The consequence has been that meteorology has had little help from physicists and mathematicians as such, and has had to depend, at least in Britain, on the relatively small band of meteorologists in Government employ. Let me say, however, that we are grateful for the help which we have received from physicists, especially from those who were brought into contact with meteorology during the War. In spite of the fact that meteorology has not been able to make use of the recent discoveries in pure physics, there has been in the last twenty-five years as fundamental a revolution in our ideas of the atmosphere as has taken place in our ideas of electricity and matter. Unless I am very much mistaken, however, these fundamental changes in our conception of the atmosphere, both as a whole and in its parts, are

little known outside the small band of professional meteorologists. I therefore welcome this opportunity of bringing them before the members of Section A of the British Association.

THE THERMAL STRATIFICATION OF THE ATMOSPHERE.

The fact that the temperature of the air decreases as we ascend in the atmosphere has been known from time immemorial, but our real knowledge of the temperature of the free air dates only from 1898, when Teisserenc de Bort introduced his *ballons-sondes*, which carried self-recording instruments to heights in the atmosphere up to that time never attained and from which no information was then available.

The initial success of Teisserenc de Bort in his epoch-making discovery of the stratosphere attracted great attention to his investigations. His methods were introduced into other countries, and an intense investigation of the upper atmosphere, with an International Commission to guide and encourage it, was inaugurated. In Britain, Mr. W. H. Dines did Trojan service in the cause, and his observations and deductions are outstanding in the mass of data accumulated in many parts of the world. Naturally the conditions over Europe and North America were investigated in the greatest detail, but every opportunity has been taken by meteorologists to obtain upper-air data from all parts of the world. In addition to the regular observations undertaken in most countries having an organised meteorological service, expeditions have gone out specially to investigate the upper atmosphere over the oceans and over tropical Africa, and nearly all recent polar expeditions have included this investigation amongst their scientific activities.

There are, of course, large tracts of the earth's surface above which no observations have yet been made, but some, if only a few, observations have been made in all meteorologically important areas, including both polar regions. It is on the results of these observations that we base our conception of the thermal structure of the atmosphere, and meteorologists have attempted from them to generalise the conditions in all parts of the world. The most important generalisation of this kind has been made by Sir Napier Shaw and published in the form of diagrams in his book, "The Air and its Ways."

Probably every one here is familiar with the main results of these investigations. The atmosphere, which itself is an extremely thin film of air, is composed of two shells surrounding the earth. In the lower of these shells, called the troposphere, the temperature decreases as one rises in the atmosphere, and the air is warmer over the equator than over the poles at corresponding heights. In the upper shell, called the stratosphere, the temperature conditions are entirely different. There is little or no change in temperature with height, and the horizontal change of temperature is reversed, the temperature at the same height in the stratosphere decreasing as one passes from the poles to the equator. At the earth's surface the mean

¹ From the presidential address delivered at Southampton on August 28, before Section A (Mathematical and Physical Science) of the British Association.

annual temperature near the equator is 27°C . and at the poles -23°C .; i.e. the equator is 50°C warmer than the poles. At twenty kilometres above the surface the temperature over the equator is -80°C , and over the poles -30°C .; that is, the temperature difference between the equator and the poles is the same in amount at the surface and at a height of twenty kilometres, but in the former case it is the equator which is the warmer, while in the latter it is the polar regions—a truly remarkable reversal.

The surface of separation between the two shells, called by Sir Napier Shaw the "tropopause," is extremely sharp. There is no region of transition. The stratosphere sits on the troposphere like a layer of oil on a layer of water. The boundary is, however, not horizontal, and therefore not exactly concentric with the earth's surface, being higher at the equator than at the pole. In other words, the lower atmospheric shell, the troposphere, is thicker at the equator than at the poles. At the equator it is nearly twenty kilometres thick, while at the poles it thins down to a layer less than six kilometres thick in the summer and less than four in the winter.

I have already said that in the troposphere the temperature decreases as one ascends. The magnitude of this decrease varies from place to place and from time to time, but one remarkable result has come out of the investigation, and that is that the average decrease is practically the same in all parts of the world. Near the ground the conditions are complicated; here the rate of decrease is largely affected by such factors as the kind of surface, whether land or water, the time of day and the time of year. If we omit for this reason the two lower kilometres of the atmosphere, we are able to state that the rate of decrease of temperature with height, to which I shall refer as the "lapse rate," is the same in all parts of the world, from the equator to the poles. The lapse rate is not the same at all heights, but increases regularly as one ascends. Between two and four kilometres above sea-level the rate of decrease is 5.6°C for each kilometre of ascent; the rate is greater at greater heights, until towards the top of the troposphere, say between six and eight kilometres, the rate is 7.1°C per kilometre.

The importance of these results lies in the bearing they have on the possibility of vertical motion in the atmosphere. Whether air will rise or fall as the result of differences of temperature depends not only on an initial difference of temperature but also on the lapse rate in the surrounding atmosphere. When dry air rises its temperature falls on account of adiabatic expansion 10°C . for each kilometre of ascent. From the observed values of the lapse rate given above, it will be seen that if a mass of air is as much as 10°C . warmer than its surroundings it cannot rise much more than two kilometres before it has no buoyancy left. The question of ascending and descending air is, however, very complicated on account of the condensation of the water vapour carried with it. The vertical motion of the atmosphere cannot be determined simply from consideration of the lapse rate of temperature in the atmosphere. We have also to take into account the pressure and vapour content of the moving air. This can best be done by considerations of entropy.

Sir Napier Shaw has prepared diagrams showing the entropy throughout the normal atmosphere. These show surfaces of constant entropy which are nearly horizontal, but they slope upwards from the equator to the poles, especially in the lower layers. If these surfaces could be made visible, we should see a series of layers lying one above the other like the strata in a geological specimen of stratified rock.

In all movements of the air in which heat is neither added nor extracted—for example, by condensation or radiation—it must travel along an isentropic surface. Even if condensation takes place, the amount of heat added is usually so small that the air can only move to a neighbouring isentropic surface slightly higher in the atmosphere. These isentropic surfaces act like physical restraints to the air, tending to prevent its moving in any but an almost horizontal direction. The effect is almost exactly as though the atmosphere were definitely stratified in nearly horizontal planes, so that all motion of the air must take place along the strata in which it started.

This is what I mean by the thermal stratification of the atmosphere, and it is a new idea in meteorology, for it rules out ascending and descending currents as a direct consequence of the normal temperature distribution in the atmosphere. That ascending currents do occur and play a large part in atmospheric processes is, however, a matter of both observation and inference. We can actually see them taking place whenever we observe well-developed cumulus clouds, and we infer them from the large amounts of precipitation which we measure, for appreciable precipitation can only be accounted for on the assumption that air is rising in the atmosphere and cooling by adiabatic expansion. These ascending currents are possible in the stratified atmosphere only if the air taking part in them receives sufficient heat on its ascent to raise its entropy at least to that of the surrounding atmosphere at each level. Heat is supplied by condensation of water vapour, but normally air does not hold sufficient water vapour, even when saturated, to supply the requisite heat, and so cannot pierce the normal stratification. It sometimes happens, however, that the stratification is less pronounced than at other times. The greater the lapse rate the less the stratification, and by increasing the lapse rate sufficiently the stratification can be reduced to such an extent that there is sufficient water vapour to supply the heat required. When this occurs the atmosphere becomes unstable to saturated air and ascending currents take place, generally with considerable violence.

Such conditions give rise to thunder-storms, which occur, as is well known, only when the lapse rate has been abnormally increased, generally by the heating of the surface layers faster than the layers higher in the atmosphere. Also in equatorial regions over the ocean, where the air is very hot and also very humid, there may be sufficient water vapour in the air for it to rise through the normal stratification. This is the origin of the squalls and heavy rain in the Doldrums. From this it will be seen that the ascent of air through its environment is not a normal phenomenon, but does occasionally occur in special circumstances.

The descent of air is an entirely different matter, for there is no process which extracts heat from a

descending current equivalent to the process of condensation which supplies heat to an ascending current. Yet air cannot descend through the stratification without the necessary heat being extracted. On the other hand, we do know that air descends, for the air which goes up in the ascending currents, or rather an equivalent amount, must come down somewhere. The solution of the problem is that air practically never descends through its environment, but comes down by the gradual subsidence of a whole column. This is generally brought about by the air at the bottom of the column spreading under the surrounding air and so lowering the air above in a way to be described in greater detail later.

If now we consider the undisturbed atmosphere in different parts of the world, we find that each has its own stratification, which is mainly determined by the local radiation. At the equator the stratification is not so close as at the poles, and equivalent strata are higher in the atmosphere the farther we move from the equator. If a large mass of air is transported as a whole without gain or loss of heat, no change in entropy occurs, and therefore it retains its original stratification. It is therefore clear that if masses of polar and tropical air are brought together the strata will not fit. The process is something like removing two geological specimens from different parts of a stratified rock and then placing them side by side. We can recognise the surface where the two masses meet by the discontinuity in the strata; in geology such a surface of discontinuity is called a fault. We shall consider later the consequence of bringing together masses of air of different origin in this way, and it will be shown that they interact like separate fluids, but throughout the resulting motion they retain their stratification, although this stratification becomes modified and distorted.

This idea of the stratification of the atmosphere which has caused us to recognise that ascending and descending currents are relatively rare occurrences raises new problems as to how the solar energy is converted into the kinetic energy of winds. This leads me to the second subject of this address.

THE MECHANISM OF THE ATMOSPHERIC HEAT ENGINE.

Brunt has calculated from considerations of wind and atmospheric friction that 25×10^{11} kilowatts of energy are required to maintain the motion of the atmosphere. It is generally agreed that this energy is derived from the solar radiation which falls on the earth, the atmosphere itself acting as a gigantic heat engine to convert the solar energy into the kinetic energy of the winds. How the atmospheric heat engine works is the problem which we are now to discuss.

Until quite recently this problem seemed to present no difficulty. All atmospheric motion was referred in one form or another to the ascent of warm air through cold air and the descent of cold air through warm air. The so-called general circulation of the atmosphere was considered to be the direct consequence of the ascent of warm air at the equator and the descent of cold air at the poles, there being a permanent circulation from the equator to the poles in the upper atmosphere, with a return flow in the surface or middle

layers. Similarly cyclones were considered to form in regions where the air is warmer than the surrounding air, with a consequent upward motion of the warm air through its colder environment. The anticyclone, on the other hand, was considered to be a region of cold descending air. Thus cyclone and anticyclone were regions of ascent of warm and descent of cold air respectively.

I have already shown, however, that the thermal stratification of the atmosphere, except in the Doldrums and occasionally in other regions, is prohibitive of such ascending and descending currents. Further observations have shown that there is no direct flow of air from the equator to the poles in the upper atmosphere, and measurements of temperature in cyclones and anticyclones have shown that the former are not warm and the latter are not cold.

Although the old ideas were wrong in detail they were, of course, right in principle, for the potential energy inherent in masses of air at different temperatures must be the origin of the kinetic energy of the winds, the difference in temperature between the equator and the poles being responsible for the general circulation of the atmosphere, and the difference in temperature between neighbouring masses of air for the energy of cyclones and anticyclones. The only question is, how does the transfer from potential to kinetic energy take place?

The solution of the problem was given by Margules in a series of papers, commencing in 1903, in which he investigated the energy developed in storms. Margules' work leads to an entirely new idea as to the method by which solar energy is converted into the kinetic energy of atmospheric motion. Instead of warm air rising vertically like the warm gases in a chimney, drawing air in at the bottom and delivering it at the top, we see two bodies of air, one warm and the other cold, brought side by side, then the cold mass slowly subsiding and pushing its way as a wedge of cold air under the warm air, which is partly raised and partly drawn in above to replace the cold subsiding air. In the process the centre of gravity of the whole moving mass is gradually lowered, so providing the energy for the motion which we recognise as winds.

The essential difference between the new and the old idea is that the two masses of air, in which the difference of temperature is the cause of the motion, never mix. We start with the two bodies of air side by side, with a surface of sharp discontinuity between them. In each body there is a different stratification of isentropic surfaces. In the warm body of air the corresponding isentropic layers are all lower than in the cold body of air. As the cold mass subsides its isentropic layers are lowered, while as the warm air is raised its isentropic layers are raised with it; but the surface of discontinuity between them, which I have previously likened to a geological fault, is a sliding surface, and no air crosses it. The sliding motion does not cease until either the corresponding isentropic layers on the two sides have joined up across the surface, which then ceases to be a surface of discontinuity, or until all the warm air has been raised above the cold air and the surface of discontinuity becomes a horizontal plane. The two masses are then in equilibrium without any mixing having taken place.

SURFACES OF DISCONTINUITY.

The process which I have just described would take place very rapidly on a stationary earth, and in a short time the surface of discontinuity would disappear in the manner described or appear as a horizontal surface with all the cold air underneath and all the warm air above. But in the atmosphere we find inclined surfaces of discontinuity persisting for days together, and others which are apparently permanent. This arises from the effect of the rotation of the earth, which we have so far neglected, but which introduces new forces when air is in motion.

A mathematical investigation of the conditions governing the air motion at surfaces of discontinuity has shown that, on a rotating earth, the tendency of cold air to pass under warm air can be completely counterbalanced by forces due to the earth's rotation if the air on the two sides of the surface has suitable relative velocities.

We owe the mathematical investigation of this problem chiefly to Helmholtz, Margules, V. Bjerknes, and Exner.

Two bodies of air at different temperatures will remain in equilibrium side by side if suitable motion parallel to the boundary is given to the air on each side. The angle which the surface of discontinuity makes with the horizontal depends on three factors, namely, the latitude and the difference in temperature and relative motion of the warm and cold currents. Given steady motion, these three factors adjust themselves in a perfectly definite way, with the cold air lying as a rule in the acute angle which the boundary makes with the horizon.

V. Bjerknes considers that there are three great permanent surfaces of discontinuity of this kind in the atmosphere, and that the slope of the surface in each is in accordance with the discontinuities of the wind and density observed on the two sides. Taking these in turn, the first is the great surface of discontinuity between the troposphere and the stratosphere. The second surface of discontinuity is between the trade winds and the anti-trade winds above them. Bjerknes' third surface of discontinuity, which has received the name of the "polar front," is a very important one in modern meteorological theory. On the whole there is very little air motion in polar regions, and the cap of air over each pole is losing heat by radiation and so tending to subside and flow away from the pole. As the air from the polar cap flows radially outwards it is deflected to the west on account of the earth's rotation. On the other hand, in middle latitudes, from near latitude 30° to the polar circle, the air is moving in an almost unbroken stream from west to east. Relative to the air in the polar cap this air is very warm. We therefore have a cold cap of westerly-moving air embedded in a warmer mass of air moving towards the east, and between the two there must be a pronounced surface of discontinuity. In such conditions the surface should slope upwards toward the pole. V. Bjerknes considers that there are such surfaces of discontinuity associated with each pole and that they are very stable. These "polar fronts" play a large part, as we shall see later, in Bjerknes' theory of the formation of cyclones.

But these are not the only surfaces of discontinuity

which play a very real part in the physics of the atmosphere. While the three surfaces just described are of a more or less permanent nature, we now recognise a constant succession of temporary surfaces of discontinuity which form and pass away in our own latitudes. Their presence is revealed in many ways. On the synoptic charts lines can be drawn which divide regions in which the conditions at the surface as regards temperature, humidity, and wind velocities are entirely different. These lines are simply the intersection at the earth's surface of the surface of discontinuity between two bodies of air.

THE ORIGIN AND STRUCTURE OF CYCLONES.

The old idea of a cyclone was tersely expressed by Sir Oliver Lodge, in a letter to the *Times* last year, as follows: "A cylindrical vortex with its axis nearly vertical, rolling along at a rate conjecturally dependent partly on the tilt, and with an axial uprush of air to fill up a central depression, which depression, nevertheless, was maintained and might be intensified by the whirl, the energy being derived from the condensation of vapour." If this were the true mechanism of a cyclone we should expect to find considerable symmetry around the axis. The air would move in a continuous stream circulating around the centre but always approaching it; in other words, the stream lines would be continuous spirals. There would also be little difference of temperature in the different parts of the cyclone, for the same air current would pass successively through all parts. In reality the conditions are entirely different. When stream lines are drawn by the aid of the wind arrows on synoptic charts it is impossible to connect them so that they circulate all round the depression; we find, on the contrary, that they are discontinuous, the stream lines in certain parts meeting the stream lines in other parts almost at right angles. Also we find large discontinuities in the temperature, each set of stream lines having its own temperature. Further, we find that the areas of rainfall are not confined to the central regions, but are broad bands radiating from the centre like spokes in a wheel, showing that the ascending air is not taking place mainly in the central region.

As the result of recent work we now recognise a structure in a cyclone which was unknown a few years ago. We owe this new knowledge largely to the work of J. Bjerknes and his assistants in the Bergen Geophysical Institute.

We are being forced more and more to recognise in cyclonic depressions the meeting-place of polar and equatorial air. Each body of air is stable to vertical currents within itself, but where the two masses meet, readjustment is necessary; the surfaces of discontinuity tend to set themselves at the angle necessary for stability under the existing condition of velocity and temperature. This involves the bodily raising of the warm air over the cold air and a general sinking and spreading out of the cold air. The energy for the process is derived from the conversion of potential energy into kinetic energy, as the centre of gravity of the air as a whole is slowly lowered during the readjustment of the air masses. The energy derived from the condensation of water vapour is a very insignificant part of the energy developed in a cyclonic depression.

It must be admitted that we are still far from a complete understanding of the mechanism of cyclonic depression; on the other hand, we now know some features which are common to all depressions, and we have a much clearer idea of the source of the energy and the conditions necessary to their production. We have to imagine that in polar and tropical regions the air is relatively stagnant, and so has an opportunity to reach the state of thermal equilibrium appropriate to those regions. As already stated, the atmosphere is only a thin film, and we picture large areas or slabs of this film breaking away from their proper locality and moving into middle latitudes. Apparently the detached films move as a whole, at least to a considerable distance within the stratosphere. When two such portions of the atmospheric film come into juxtaposition they are not in equilibrium relative to one another, and readjustment must take place. The surface of contact remains more or less intact, but the cold air tends to sink and undercut the warm air, while the warm air slides up the surface of discontinuity. The whole motion takes place on the revolving surface of the earth, and the forces called into play by this revolution result in the air movement taking place in what appears to be a great vortex. The energy of the winds is derived mainly from the readjustment of the centre of gravity of the air mass considered as a whole, although the latent heat of condensation provides some additional energy by supplying heat to the warmer air as it ascends the slope of the surface of discontinuity. It will be admitted, I think, that this is a radically new idea regarding the mechanism of a cyclone.

All that I have said so far refers to the cyclonic depressions of middle latitudes. As to whether the mechanism of tropical cyclones is the same or whether we have here something more of the nature of the process described by Sir Oliver Lodge, meteorologists are not yet agreed. We need more observations, especially of the conditions in the upper air over tropical cyclones, before this question can be decided. At present we must leave it an open question.

These new ideas have had a far-reaching effect on the practical applications of meteorology, especially in the domain of weather forecasting. The old method of weather forecasting was mainly empirical and based on the work of Abercrombie. Abercrombie had sketched the distribution of weather about centres of high and low pressures, and forecasting was based on the determination of the movement of these pressure distributions when they appeared on the weather chart, the assumption being made that as the pressure system passed over a place the normal sequence of weather would be experienced.

Now the forecaster has much more knowledge of what I may call the anatomy of a depression. The pressure distribution is of course still the main factor, but the forecaster searches his chart for indications of the surfaces of discontinuity, and examines the characteristics of the air masses to see whether they are of polar or equatorial origin. In this way he is able to determine the structure of the cyclone and whether it is developing or dying. Having determined where the surfaces of discontinuity are situated, he is able to say where rain may be expected, and he knows what weather changes will accompany the passage of each surface of discontinuity as it moves over the surface of the land. He is aided in this by observations taken in the upper atmosphere by means of pilot balloons and aeroplanes fitted out with meteorological instruments.

This has all resulted in greater confidence in the forecasts made, a confidence which is frequently justified by remarkably accurate forecasts. Unfortunately, the processes which take place in the atmosphere are extremely complicated, and perfect forecasts are still far from being attained. The progress made, however, is very encouraging, and, what is still more important, the paths along which further investigation must be made are clearly defined. Many more observations of the upper air are necessary, many more theoretical investigations have to be made in the quiet of the study, and there is room for many more experiments in the laboratory.

Dispersal of Butterflies and other Insects.

By E. P. FELT, State Entomologist of New York.

A 2000-mile air trip appears almost impossible for an ordinary butterfly. It is still something of a feat for an airplane. Many insects are perfectly at home in the air, fly freely here and there, and are usually believed to flit from flower to flower or from one near-by locality to another. Rarely do we think of their travelling considerable distances, and under ordinary conditions it is very difficult, if not well-nigh impossible, to establish the fact that long trips may be made by individual insects. There is a romance about these journeys as well as a practical aspect. The facts are not difficult to understand, and it should be comparatively easy for readers to arrive at satisfactory conclusions.

The "Monarch" butterfly (*Danais plexippus* L.) is one of the commonest and most noteworthy insect travellers. Its large size and tawny colour with black and white markings make it comparatively easy to

recognise even at some distance. This is the very common "milk-weed" butterfly of the northern United States and southern Canada, the insect which occasionally attracts notice because of the immense swarms which appear in early autumn, apparently southward bound. The butterfly, although so common in the north temperate latitudes, is unable to survive our winters north of the sub-tropical portions of the Southern States. Consequently, the annual reappearance of this insect proves a considerable northward movement each year, though it does not establish the fact that the entire journey from Florida nearly to the Arctic Circle is necessarily accomplished by individuals. It may be the successive efforts of several generations working northward with the advance of warm weather.

A similar northward flight is known for the cosmopolitan "Painted Lady" (*Pyrameis cardui* L.) in

Europe. The butterflies cross the Mediterranean Sea, and in the opinion of Mr. C. B. Williams originate south of the north coast of Africa, since they have been seen entering Algeria from the south and have been observed crossing the Nile Valley near Cairo in thousands, coming from the south-eastern desert. He believes that all Europe north of a line through the middle of France and South Germany or Switzerland depends entirely for its Painted Lady butterflies upon African areas south of the great desert, some finding their way to northern Scotland, Scandinavia, the Shetland and Faeroe Islands, and even distant Iceland.

The above cannot explain the presence of the Monarch butterfly in the Hawaiian Islands, areas 2000 miles from the American continents, where the insect was not known prior to the establishment of its food-plant a milkweed (*Asclepias curassavica* L.), in the islands about 1850. At one time it was thought that this butterfly may have made its way to the mid-Pacific with the aid of shipping, in spite of the fact that the habits of the insect are such as to make it improbable that it could be carried with its food-plant in its early stages, or be content to remain upon a ship during an entire voyage. Furthermore, shortly thereafter this butterfly became generally established in a number of other Pacific islands, and if commercial agencies were the carriers, they certainly were very accommodating. The observations of Commander Walker of the British Navy indicate the habitual presence of these butterflies at sea among the Pacific islands and many miles from land.¹

The above facts are not conclusive as to the ability of the Monarch butterfly to negotiate safely a 2000-mile journey over the Pacific Ocean, and yet they are very suggestive. There is a remote possibility that some unusually favourable condition may have made it possible for this insect to establish itself in the mid-Pacific. It happens, however, that three other large butterflies, the Red Admiral (*Pyraus alalanta* L.), the Painted Lady (*P. cardui* L.), and the Painted Beauty (*P. virginensis* Drury), have been found in the Hawaiian Islands during recent years, and in the case of two at least not until the native food-plants had been introduced. An unusual condition may explain the presence of one insect, but can scarcely be considered as the reason for the establishment of three others many years later, particularly when in all cases the lack of a suitable food-plant appears to have been the determining factor.

The 2000-mile aerial trip of the four butterflies mentioned above still seems rather incredible, and with this in mind we would turn for a moment to the dragon-flies of the Hawaiian Islands. At least two of the larger species are widely distributed in America, and were not found in the Hawaiian Islands until comparatively recent years. Apparently the extensive cultivation of rice and taro has resulted in great expanses of fresh water in which these dragon-flies could breed, and it seems entirely reasonable to think that if the butterflies travelled on the wings of the wind, the same might be true of these dragon-flies, and that the determining factor in each case was the prevalence of conditions favourable to the propagation of the species.

Dragon-flies are well known as strong flyers, and there is at least one record of these insects appearing in large numbers in the Indian Ocean about 900 miles west of Australia and nearly 300 miles from the relatively insignificant Cocos-Keeling Islands, tiny land areas where dragon-flies are unable to maintain themselves according to Prof. F. Wood-Jones, and yet frequently visited by considerable flights of these insects, coming with northern winds, presumably from distant Sumatra.

It certainly begins to look as though we must accept the 2000-mile air trip as the most reasonable explanation of the occurrence of these insects in the somewhat isolated Hawaiian Islands, and admit that nearly half that distance is repeatedly travelled by insects journeying over the Indian Ocean. It is perhaps assumed that this is possible only in the case of strong flying insects, such as the larger butterflies and the more powerful dragon-flies. This latter does not necessarily follow. The terrible eruption of Krakatoa in August 1883 devastated that entire group of islands, they being overlaid by hot ashes approximately 90 to 180 feet thick, making it very improbable that anything living could escape, yet twenty years later some 64 species of insects were found upon this seldom visited group, and investigations by Dr. Dammerman, published in 1922, show that certain extremely small flying insects, such as thrips, were represented upon the island by some ten species. He estimates that 80 per cent. of the animals on these islands are winged. Furthermore, the work of naturalists at such outlying points as the Kentish Knock Lighthouse, some twenty-one miles from the nearest points of land, resulted in capturing, among a number of other insects, a delicate plume-moth with somewhat the consistency of a bit of thistledown. Similarly, studies at the Rebecca Shoal Light Station, itself entirely submerged and 12 miles east of the Dry Tortugas, showed the presence of such comparatively inefficient flyers as a lace-winged fly, a damsel-fly or small dragon-fly, and fragile gnats. In other words, insects with supposedly very weak powers of flight undoubtedly drifted considerable distances. Dr. W. L. McAtee records crossing Currituck Sound, N. C., a distance of 6 miles, during which caddis-flies and midges were so numerous over the water that vision was perceptibly restricted and one was constantly annoyed by the impacts of the insects against the face.

These latter records suggest that insects may drift with the wind, and the question may well be raised as to the agencies which make possible the long trips mentioned above. We have become so accustomed to a determinate migration by birds that there is a strong tendency to explain insect movements in the same manner. It is quite possible that some insect movements are direct responses to a migration impulse, but on the other hand there is no proof that such is the case in regard to some of the wanderings discussed above. The physical exertion involved in a 2000-mile trip against the wind is so great that one may reasonably question the ability of even the most powerful flying insects to accomplish this successfully. There is no question but that unusual gales may carry insects enormous distances in the same way that such disturbances force migrating birds far from their normal courses. These occasional and unusual wind currents

¹ Cf. *The Honolulu Monthly Magazine*, vol. 22, p. 221 (1886), and vol. 30, pp. 230-1 (1914).

do not appear to be the most effective in promoting the spread of insects, though they undoubtedly assist to a material extent. The observations of Prof. F. Wood-Jones as recorded in his "Coral and Atolls" indicate that dragon-flies go to sea of their own accord, and that they are not blown from the shore. He states that in periods of absolute calm of long duration one species of tropical dragon-fly may be seen hawking about over the sea twenty miles and more from the nearest land, and that he has observed numbers of this insect almost daily in a journey through dead calms all the way from Singapore to Thursday Island. He adds that strong-flying butterflies do the same, flying away from the land in a perfectly irresponsible way, and that moths come nightly to a ship's light when she is lying twenty miles from the shore. This condition obtains in other parts of the world, and is evidenced by the insect drift occasionally found along the shores of oceans and lakes in particular. These insects are not necessarily carried out over the water by strong winds. They are simply the normal population of the air which under ordinary conditions, in the case of the smaller lakes at least, would allow themselves to drift across the water, whereas a sudden chilling of the atmosphere, especially if accompanied by rain, results in driving many of them down into the water and their subsequently drifting ashore. According to Mr. C. B. Williams, Acting Chief Entomologist of Egypt, a number of insects drift many miles into the African deserts.

It is our belief that determinate flight is a comparatively small factor in promoting the spread of insects, and that in many cases this is accomplished largely by a drifting with the wind, the stronger flying species probably being able to remain in the air longer than their weaker associates. Much of this long distance spread is very probably made possible through the higher velocities of the upper air strata, the insects gaining these by the aid of convectional currents arising from heated surfaces and now known to extend to a height of at least 1000 feet above the surface. These upper air currents frequently have a velocity of 30, 50, or even 100 miles an hour, consequently a favourable wind for a relatively short time is all that is necessary to carry an insect long distances. This is probably what occurs rather frequently in the early autumn when swarms of "cotton-moths" (*Aletia argillacea* Hubn.), an insect unable to survive north of the cotton-growing area, appear at lights in the northern United States and southern Canada.

Even relatively high wind velocities would mean an insect remaining in the air a day or so, if it were to make the 2000-mile trip from the American continent to the Hawaiian Islands. This is probably within the physical powers of an insect, though it does not necessarily follow that a non-stop journey is made over such an expanse of water. There are several records of the smaller butterflies at least resting upon the surface of the ocean and successfully resuming flight. This has also been recorded of certain grasshoppers, and it appears possible that larger butterflies and even dragon-flies might do the same under extreme conditions.²

If the upper air currents are somewhat important carriers of insects, there should be some confirmatory evidence. It is perhaps sufficient to state here that

mosquitoes have been met with at an elevation of 3000 feet above the surface, grasshoppers at a height of 2000 feet, and honey-bees at approximately the same elevation. Plant spores have been recorded at an elevation of 11,000 feet. These last must have been carried up by convectional currents. Winds tend to drop over the cooler water surfaces and glaciers of the earth, and on these latter exceptionally large numbers of insects have been observed repeatedly, probably forced down by the falling temperatures. Furthermore, collectors on some of the high mountains, such as Mount Washington, have taken insects which are distinctly southern or south-western in habitat, probably carried there by the upper air currents and dropped upon these cooler mountain tops.

It is not suggested for a moment that the appearance of butterflies and dragon-flies in the Hawaiian and other ocean islands is anything more than the outcome of a somewhat irresponsible flight assisted by favourable winds. There is another phase or supposed phase of insect movement deserving notice, that is, the autumn assembling of Monarch butterflies and their apparent southward movement in considerable numbers. There are a number of records of apparently determinate movement by butterflies, mostly in the tropics, and a somewhat similar movement on the part of dragon-flies, in some cases immense numbers of insects coming under observation. These cases may represent a true migration, though this is scarcely established by available data. It is quite within the realm of possibilities that atmospheric or other disturbances may have resulted in an unusual condensation, as it were, of insect life, and that the movements observed followed a change in conditions and were in some instances at least an instinctive effort on the part of the insects to spread out or move away from each other, in order to secure better opportunities for food, either for the insects themselves or their progeny. The account by W. H. Hudson of the dragon-flies appearing in advance of the dry, cold "pampero" in the Argentine, and the record by Gatke of the millions of dragon-flies appearing in Heligoland in advance of a storm and their rapid scattering thereafter, are both very suggestive in this respect.

The fact that various natural causes result in large swarms of insects should not be overlooked in this connexion. The nearly simultaneous development of millions of mosquitoes, midges, caddis-flies, black-flies, and butterflies within a restricted area accounts for many swarms, and these must disperse in some way, if they are to live and provide for their progeny. A movement in any one direction is likely to establish a trend which might easily be mistaken for determinate migration. The observations of Prof. V. L. Kellogg in relation to the winter assembling of the Monarch butterfly in southern California, to revert to this insect once more, suggest that the swarms of this insect may be really the expression of a hibernating instinct rather than a preliminary to migration.

It may appear to some that a rather large part in the distribution of insects has been given to the winds, and comparatively little left to the physical ability and the desire or instinct of the insect. We are considering particularly those individuals which allow themselves to be carried by winds, and in most instances they are

² Cf. Seitz, *Macro-Lep., Palæarctic Region*, 1, p. 77, *Danizda plexippus*

a relatively extremely small proportion. It is very probable that many of these widely ranging forms are somewhat local, if that term is not interpreted too narrowly. On the other hand, we should not expect winds to do less for insects, forms inheriting most admirable organs of flight, than for such wingless creatures as spiders. McCook, a well-known authority, states that ballooning spiders have been found more than 200 miles from land and at elevations of more than 1000 feet. He has concluded from a study of distribution in the tropical regions that these spiders may have actually circumnavigated the globe on the wings of the wind. The known distribution of certain small insects in tropical areas likewise suggests that winds may have played a most important part in carrying these minute, fragile insects. In other words, the ability of the organism to support itself in the air appears to be a most important factor in certain types of distribution.

There is very little question but that representatives of many species of insects are carried far beyond any point where they can possibly maintain themselves. Nature is extremely profuse in her provisions for the continuance of both plant and animal life; the greater

the hazard, the more liberal the provision as a rule. It appears reasonable to conclude that winds are carrying millions of insects daily into regions where they cannot possibly survive. A few especially favoured forms may by chance find their way to an area where there are livable conditions. One of the notable instances of this kind was the appearance of a caterpillar on the first crop of tomatoes and peas raised from seed in the out-of-the-way Cocos-Keeling Islands, although it was not a native species, and the parent moth must have travelled hundreds of miles over an inhospitable ocean. A similar case came to the writer's attention recently in connexion with a small patch of corn growing in a Chilean desert. Insects are all about us. Only occasionally do we realise the frequency with which they appear in unexpected places.

Fortunately for man, many of the more destructive species find themselves unable for one reason or another to take advantage of the wings of the wind. An economic application is that insect spread may be somewhat definitely limited by the winds which prevail when other conditions are favourable for dissemination.

Obituary.

DR JOHN M. CLARKE.

JOHN MASON CLARKE, who died at Albany, New York, on May 29 last, was one of the foremost palaeontologists of America. The son of a schoolmaster at Canandaigua, New York, he was born on April 15, 1857, and received his early education in the school which his father directed. He was inclined in boyhood to the study of geology and natural history, and he proceeded in 1873 to Amherst College, Mass., where he graduated in 1877. At Amherst he came under the influence of the professor of geology, B. K. Emerson, and so entered on his life-work. He began to study in earnest the Upper Devonian rocks and fossils in the neighbourhood of his home, and while holding a succession of small teaching appointments devoted all his leisure to original research.

By the end of 1884 Clarke had made so much progress, that he felt impelled to compare his results with those of European geologists, and he went to spend parts of two years studying under Prof. A. von Koenen in the University of Göttingen. There he graduated with a thesis on Devonian geology in 1885, and after holding another small teaching post, was eventually appointed assistant to Dr. James Hall, the well-known State Palaeontologist of New York, in 1886. Thenceforward until his death he was connected with the Geological Survey of New York, becoming State Palaeontologist in 1898, and State Geologist as well as Director of the State Museum in 1904.

Clarke's earliest papers on Devonian fossils were published in 1882, and were followed by a long succession which culminated in his two classic volumes, "The Early Devonian History of New York and Eastern North America," published by the Geological Survey of New York in 1908-9. At the same time he studied the Devonian fossils not only of Germany, but also of Brazil, Argentina, and the Falkland Isles. Among his

official duties he was also concerned with several other Palaeozoic faunas, and he became the recognised authority on Palaeozoic invertebrata in America. With Dr. James Hall he published "An Introduction to the Study of the Genera of Palaeozoic Brachiopoda" in 1893-94; and with Dr. Ruedemann a monograph of "The Eurypterida of New York" in 1912. Both these are works of reference of permanent value.

In later years Clarke made good use of his ripe scholarship in considering some of the wider problems of the science to which he had devoted his life. As first president of the Palaeontological Society of America, in 1911 he delivered an address on "The Philosophy of Geology and the Order of the State," and in 1921 he published a little memoir entitled "Organic Dependence and Disease." He applied his science to questions of state control, and argued that it pointed to individualism, not socialism, as the essence of progress.

Clarke was an attractive personality with very wide interests beyond those of his special work. As head of the State Museum he also controlled the science division of the department of education, and he was associated with many other organisations in the city of Albany. He will be mourned not only as an eminent man of science, but also as a model citizen.

A. S. W.

MR. D. R. STEUART.

DANIEL RANKIN STEUART, late chief chemist to the Broxburn Oil Co., Ltd., died at his residence, Blackhall, Edinburgh, on August 1. He was a well-known figure in scientific circles in the east of Scotland, and was a recognised authority on the chemistry and technology of shale oil and petroleum. Born at Bogside, Lanarkshire, in 1848, he studied botany and geology in his early youth, and, for reasons of health, spent some ten years in the open-air pursuits of gardening and farming, he received his chemical training at

the University of Edinburgh under Crum Brown, at Glasgow under Dittmar, and finally at Munich. His connexion with the shale oil industry, destined to be a lifelong one, began about 1875, when he became a laboratory assistant to the late Sir George Beilby at the Oakbank Oil Works. In 1877 he was appointed chief chemist to the Broxburn Company, and retired from that post five years ago.

Mr. Steuart was a strenuous worker, endowed with a mind of exceptional intellectual insight and power. His writings are well known, and include a number of articles, contributed to the Transactions of the Society of Chemical Industry, on the shale oil industry, petroleum, and brown coal; some of these are of practical interest, others in speculative vein. To the same Society he read a paper entitled "The Oxidation of Mineral Oils," and edited and read one by his nephew, Mr. B. Steuart, on "The Composition of Shale Naphtha." It was one of his regrets that his routine duties did not permit him to devote more time to organised research; he, however, strongly advocated the desirability of industrial research being taken up by qualified university workers. That his eminence as an authority on shale was widely recognised is attested by articles written by request to "Economic Geology" (U.S.), Ure's "Dictionary," Muspratt's "Chemistry," Thorpe's "Dictionary of Applied Chemistry," and an important contribution to the memoirs of the Scottish Geological Survey entitled "The Chemistry of the Oil Shales." In the last mentioned he propounded a theory referring to the origin of oil shales.

Mr. Steuart's humane instincts led him, in 1890-95, to direct public attention to the number of deaths caused by the use of low flashing burning oils in lamps. He wished the standard of flash point to be raised from 73° F. to 100° F., and gave evidence on the subject before a Select Committee of the House of Commons during the reading of the Petroleum Bill. The measure was unsuccessful, but as the light constituents of petroleum (the cause of low flash point) afterwards became valuable as motor fuel, Mr. Steuart had the satisfaction of seeing burning oils made safer by the elimination of much of the danger in the refinery.

R. H. FINDLATER.

PROF. O. BREFELD.

THE death was recently announced of Prof. Oscar Brefeld, the founder, and for fifty years a leader, of modern mycology. Born at Telgte in Westphalia, on August 19, 1839, the son of a wealthy pharmacist, whose business he was intended to inherit, he early took an interest in the lower plants, but it was not until 1868 that he began his mycological studies in earnest. At the outset he realised the necessity of sterilising the culture media and the apparatus, and of studying microbes and spores as individuals. For this purpose he introduced gelatine—which he replaced later by agar-agar—and devised the method of pure culture by thinning the medium so as to grow a colony from a single cell under continuous microscopic observation. Thus he laid the foundation of all subsequent microbiological study ten years before R. Koch took up the inquiry.

NO. 2914, VOL. 116]

In 1870 the contemporary work of Pasteur led a Munich brewer to seek the assistance of Brefeld. Here he gained experience and a crop of fruitful ideas, but his work there was cut short by the Franco-Prussian war. From the siege of Paris he was invalided home after an attack of typhus and prosecuted his studies in Berlin. Here he took his doctor's degree, and in 1872 published the first volume of his great life work, "Botanische Untersuchungen aus dem Gesamtgebiete der Mykologie" (18 vols.), known as the mycologists' Bible. The following year saw the publication of his epoch-making researches on the Ascomycetes, especially on the cultivation of the blue mould *Penicillium glaucum* from a single spore to a mycelium with complete fructification. One cannot here go through the contents of successive volumes, but his important work on *Bacillus subtilis*, undertaken for the Prussian Government in 1878, demands mention. Brefeld did not, however, pursue bacteriology, feeling that his medical knowledge was too slender. Robert Koch was therefore substituted to become the "German Pasteur."

Brefeld, after habilitating as privat-docent in Berlin, became, in 1876, professor at the Forestry Academy in Eberswalde. Here he lost the sight of one eye. As a consequence of the "Kulturkampf" he was urged by the Government to become professor of botany at Münster in Westphalia. Here he continued to publish the most valuable work, until his removal to Breslau in 1898. In the year before the War, Brefeld resided in Berlin, where he lectured; but he became completely blind and had to resign his professorship.

Brefeld was a hard worker, entirely bound up in his life-work. He did not care to have pupils, but he trained a succession of assistants, among whom may be mentioned the Germans, Zopff, Alfred Möller, and R. Falck; the Norwegians, Holtermann and Sopp, the Swiss, Von Tavel; and the Hungarian, Gyula de Istvanffy. We are indebted to an article by Dr. Sopp in a recent issue of *Nature* for the details of Brefeld's life.

We learn from the *Chemiker-Zeitung* with much regret that on August 4, shortly before his fifty-fifth birthday, Dr. Friedrich Auerbach, younger brother of the physicist Dr. Felix Auerbach of Jena, and well known as the collaborator with Abegg in the "Handbuch der anorganischen Chemie," died suddenly of heart failure. Auerbach studied at his native town, Breslau, under Ladenburg, to whom for a while he acted as assistant, after which he was engaged for several years in industrial work. But his real interest lay in scientific investigation, and in 1903 he returned to Breslau, where Abegg had recently begun to build up a flourishing school of chemistry. Shortly afterwards he was transferred to the Imperial Health Department. At Breslau, Auerbach devoted his attention chiefly to physical chemistry, and he published many papers dealing with the theory of electrolytic dissociation and the theory and practice of the electrometric titration of acids. After the death of Abegg in 1910, Auerbach undertook the onerous task of editing the "Handbuch der anorganischen Chemie." Before the War he was a member of the International Association of Chemical Societies.

Current Topics and Events.

A LARGE party from Section D (Zoology) of the British Association visited Hayling Island on Monday for the formal opening of the British Mosquito Control Institute which has been built there by Mr J. F. Marshall. Anti-mosquito work was commenced at Hayling in 1920, and we have on several occasions referred to the very valuable results achieved. By draining and other operations, the mosquito nuisance in the district has been almost entirely removed, and the measures adopted have been followed with success at other places around the coast. Mr Marshall's work in connexion with both salt-water and fresh-water mosquitoes has become so widely known that inquiries from medical officers and others continually reach him from many parts of the country, and numerous people interested in the subject have visited Hayling to see his laboratory and his control work in inter-tidal and other areas. This led to the erection of a building containing a demonstration museum, laboratory, drawing office, photographic room, and other facilities for study and research in various branches of mosquito control work. The building, the design and equipment of which are based upon five years' experience in the laboratory and the field, is the first example of an institution devoted exclusively to what may be termed the non-medical side of mosquito investigation. Sir Ronald Ross, in an address at the opening ceremony, described the growth of the organisation at Hayling and expressed high appreciation of Mr. Marshall's work, both as to its scientific value and practical service. We hope to give some further particulars of the Institute and the opening ceremony in our next issue.

THE recommendations of the Committee on the use of preservatives and colouring matters in food have already been noticed in these columns (February 14, p. 217). It will be remembered that the Committee considered that the use of boric and salicylic acids and their salts should be prohibited completely, that sulphurous and benzoic acids and their compounds should be permitted in certain articles of diet in quantities not exceeding a definite limit which varied according to the food, and that a list of permissible colouring matters should be drawn up. The Minister of Health has now issued regulations under the Public Health Acts dealing with this subject. (The Public Health (Preservatives, etc., in food) Regulations, 1925. Statutory Rules and Orders 1925, No. 775, and Circular 606. London: H.M. Stationery Office, 3d. and 1d.) Certain previous regulations as to the use of preservatives in butter and cream are revoked, and the use of any thickening substance in the latter is forbidden. The foods in which preservatives are allowed, whether sulphur dioxide or benzoic acid, and the maximum amount permissible, are given in a schedule: it will be remembered that the articles of diet concerned are sausages, fruit preparations, wines, non-alcoholic beverages, syrups, gelatin, coffee extract, pickles and sauces. As regards colouring matters, a short list of those forbidden has been

drawn up and includes certain metallic salts, a few coal-tar dyes and gamboge. The regulations include a section prohibiting the sale as a preservative of any article the use of which as a preservative is forbidden, and also details as to the labelling of certain of the food products in which a preservative is permissible and of articles sold specifically for use as preservatives. The regulations come into force on January 1, 1927, except in the case of butter and cream, where their operation is postponed for a further year.

THE issue of the Journal of the British Science Guild for August contains a valuable report, prepared by a committee of the Guild, on the supply of trained research workers in Great Britain and their utilisation in industry. According to it, in the year 1923-24, the number of full-time students of science at British universities was 60 per cent greater than in 1913-14; the number of students who obtained science degrees was three times, and the number engaged in full-time scientific research four times, the corresponding numbers in the former year. While the universities are in this way doing what they can to supply the industries with the research workers they require if they are to hold their positions against their competitors, the industries themselves are doing little to absorb the trained men available. This is particularly the case in the chemical industry, and the Department of Scientific and Industrial Research has taken steps to reduce the number trained in this subject. The committee recommends that a staff of research workers should be maintained in a national institution, and that any firm should be able to secure the services of one or more of them for work at its own private problems.

IN a recent address to the American Institute of Electrical Engineers, published in the June issue of the Journal of the Institute, Mr E. M. Herr discussed the future of railway electrification. Up to June 1924, the electric locomotives built and under construction in the world numbered 2351, of which the aggregate horse power was more than four million. Of these locomotives 905 were operated by direct current. In Italy there were 504 locomotives, and in the United States 465. Then came France, Germany, and Switzerland with 366, 304, and 214 locomotives respectively. No other country had so many as 150 electric locomotives in service. Great Britain, however, has constructed and is constructing a large number of electric locomotives for use overseas. One curious development in the Italian railways is the use of portable substations. These are of use in the event of a breakdown of an ordinary substation or when part of the line gets overloaded. All the devices, including 100,000 volt transformers, are carried on a railway bogie waggon frame which can be coupled to an ordinary train and travel at a speed of 50 km (31 miles) per hour. At present they are in regular use in places where the substations have not yet been constructed. One of these substations is being exhibited at the Grenoble Exhibition.

IN an address to the Water Power Congress held at Grenoble in July, a translation of which appears in *Engineering* for August 14, Mr. Bouchayer discusses the regulation of the import and export of electrical energy between neighbouring countries. In France, the demand for electric energy greatly exceeds the supply, and so the main problem is concerned with the import of electrical energy from abroad. Switzerland supplies most of the imported energy. Belgium supplies energy to both works and distributing stations. A small amount of energy also is transmitted across from Italy and Spain. The amount sold to French consumers in 1923 by the Swiss hydro-electric industry amounted to 521 million kilowatt hours and is constantly increasing. This export is watched with some misgivings by the Swiss Federal Council. They are afraid that the use of cheap hydraulic power may enable a foreign industry to compete successfully with one of their own. Should there be a drought, the export "permits" limit seriously the amount of energy that can be transported, and this may be very awkward for the foreign consumer. The suggestion is made that the Swiss law should provide for an indemnity when an authorisation is withdrawn. From the point of view of the French authorities, the import of cheap energy may prevent the development of French hydro-electric power, which, as it has in general to be transmitted over long distances, cannot be sold so cheaply. Mr. Bouchayer suggests that an inquiry should be held and also that a tax should be put on energy imported over a distance of 100 km. (62 miles) into France. The tax suggested is 0.005 franc per kilowatt hour. Electrical energy should only be imported within the limits required by the national interest.

THE Rowett Research Institute has recently issued Volume I. of Collected Papers consisting of 62 communications to a score of different journals. All but two of these have been published within the last five years. The wide distribution of these publications, serving as they do the sciences of agriculture, bacteriology, chemistry, and medicine, make it most convenient to have all the publications in one volume. The name of the editor of the volume, Dr. J. B. Orr, Director of the Institute, is associated with half the papers. The field of research covered by a number of investigators in four different departments is naturally extensive, but the activities of the Institute as a whole have been focussed on problems of nutrition. Although much work has been published on the subject of calorimetry, the staff, while recognising the importance of this aspect of nutrition, realised that other essential factors had in the past been neglected. Several papers are devoted to work on vitamins, but this work seems to have stimulated a reluctance to accept the explanation of deficiency of these accessory factors as the chief cause of lack of growth and of such diseases as rickets, attributed to vitamin deficiency by the majority of modern investigators. Other possible explanations have therefore been sought; the neglected field of mineral metabolism offering the most scope for work. The possibility of a lack in

the food supply of any of the normal mineral constituents of the animal body, *e.g.* calcium, phosphorus, iron, etc., and the effects produced by deficiencies of these substances, are complicated by hypotheses of the necessity of rigid mineral balances in the food, thus presenting a very wide field for investigation. The Rowett Research Institute is to be congratulated on the whole-hearted way in which the staff has attacked these problems, for much more work on animal nutrition is urgently required by our oldest industry to make good the deficiencies arising from new animal environments. It is well to remember, however, that this is the output of only five years' work, and the too speedy application of scientific results to agricultural practice has its dangers.

THE British Research Association for the Woollen and Worsted Industries, Torrington, Headingley, Leeds, is awarding next session a number of research fellowships and advanced scholarships. The fellowships will be of the annual value of not more than 200*l.* each and are tenable at an educational institution or at a works. The scholarship grants are such as to cover expenses and maintenance and are intended to enable students to specialise after completing their secondary or university education; they are also open to factory workers. A wide choice of studies is available to textile students who enter for these scholarships.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned. An assistant lecturer in agricultural zoology in the department of agriculture of the University of Leeds—The Registrar, The University, Leeds (September 14). A lecturer in metallurgy in the University of Liverpool—The Registrar, The University, Liverpool (September 15). A secretary to the Public Instruction Committee, Jersey—The President, Public Instruction Committee, Greffe Office, Jersey (October 1). The Jenner Memorial Research Studentship at the Lister Institute of Preventive Medicine—The Secretary, Lister Institute, Chelsea Bridge Road, S.W.1 (October 3). A director of the new pharmacological laboratories of the Pharmaceutical Society of Great Britain—The Secretary, Pharmaceutical Society of Great Britain, 17 Bloomsbury Square, W.C.1 (October 5). A senior lecturer in philosophy in the University of Melbourne—The Agent-General for Victoria, Melbourne Place, Strand, W.C.2 (October 15). A director of the department of medical entomology, and lecturer on noxious and venomous animals, at the London School of Hygiene and Tropical Medicine (Division of Tropical Medicine and Hygiene)—The Secretary of the School, 23 Endsleigh Gardens, N.W.1 (October 31). An assistantship in the Department of Logic of the University of Glasgow—The Secretary, The University, Glasgow. A junior scientific assistant in the ignition and electrical department of the Royal Aircraft Establishment—The Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (quoting A. 78). A chemist in the establishment of a large textile firm—The British Woollen Research Association, Torrington, Headingley, Leeds.

Our Astronomical Column.

PLANETARY TEMPERATURES—Dr. W. W. Coblentz's pioneer work on the measurement of the heat of the stars by means of the vacuum thermocouple is well known. In conjunction with Dr. Lampland of the Lowell Observatory, he has recently made similar observations of the heat radiation of the planets and the moon, and the results are published in the June and July issues of the *Journal of the Franklin Institute*. The substances water, quartz, glass, fluorite and rock salt are found to be practically opaque beyond the wave-lengths 1μ , 4μ , 8μ , 12μ , and 23μ respectively, whilst the atmosphere itself is opaque beyond 15μ . By the use of screens made of the materials mentioned, it was therefore possible to obtain thermocouple measurements of the radiation incident in the regions 0.3μ to 1μ , 1μ to 4μ , 4μ to 8μ , 8μ to 12μ , and 12μ to 15μ . From these measures the true planetary radiation could be found by subtracting the reflected solar light (0.3μ to 1μ) from the total radiation, and the spectral composition of the remainder enabled the planetary temperature to be estimated.

The most interesting of the results are those referring to Venus and Mars. Observations on Venus showed that when the bright phase was a narrow crescent, the dark part emitted an intense planetary radiation (in the region 8μ to 12μ) amounting per unit area to one-tenth of the total radiation from the bright crescent. It is pointed out that this suggests either a short rotation period for the planet or a hot interior. The region near the south cusp was hotter than that near the north, but long-continued observations will be necessary to settle whether this is a seasonal effect. If it is seasonal, the possibility of determining the position of the axis of rotation is foreshadowed.

Extensive observations of Mars were made during the opposition of 1924. The dark regions were found to give an appreciably higher temperature than the bright regions. The noon-day temperature of the bright regions on the equator came out as 5°C , that of the adjacent dark regions as 20°C . At the same time the east (sunrise) limb gave -45° , the west (sunset) limb 0° . These results show a huge diurnal range of temperature for points on the equator, indicating a rare atmosphere. The temperature of the north polar region was found to be steady at about -70° , but that of the south polar region rose gradually from -68° to $+10^\circ$ as the summer season in the southern hemisphere advanced. The temperature of the night-side is thought to be probably below -70°C . The integrated temperature of the whole disc was -30°C for the month of July 1924.

THE GRONINGEN ASTRONOMICAL LABORATORY.—This institution, founded by Prof. Kapteyn, is continuing its labours under the direction of Prof. P. J. Van Rhijn. Publications 36, 37, 39 have recently come to hand. No. 37 is a discussion of the systematic errors of the trigonometrical and spectroscopic parallaxes published by several observatories. It is well known that systematic differences exist in the parallaxes found at different observatories. Prof. Van Rhijn seeks to determine the true values by correlating angular proper motions with linear velocities for different groups of stars. Systematic errors in the assumed trigonometrical parallaxes necessarily enter also into the spectroscopic ones, since the curves of line-intensity are based on trigonometrical results.

Prof. Van Rhijn revises the Groningen statistical parallaxes given in publication 34, reducing them on the average by 10 per cent. Comparing them with the Victoria spectroscopic parallaxes, he finds the following corrections to the latter: Spectral types F, G, K, correction $-0.005''$; type M $+0.004''$.

Publication 36 is a study of the number of stars of

each spectral class between definite limits of proper motion, visual magnitude and galactic latitude.

No. 39 is a list of 656 proper motions of faint stars deduced from Helsingfors plates. The largest two centennial motions are $129''$ (mag. 10.2) and $38''$ (mag. 13.1).

MULTIPLE STARS—F. Henroteau, of the Ottawa Observatory, contributes an interesting paper to the July issue of *La Science moderne* describing some multiple stellar systems. Many of these are studied spectroscopically, and also photometrically with the photo-electric cell.

σ Scorpii consists of a Cepheid, the pulsation period of which is about 6 hours, having a companion with orbital velocity of some 35 km/sec and period 33 days. There is a more distant companion the period of which is 12 years. The motion of the Cepheid in this large orbit causes its light variations to be alternately accelerated and delayed, owing to the change in its distance.

σ Cygni is stated to have a density $\frac{1}{100}$ of the sun's, and a mass 10 times the sun's, while its companion has a diameter $\frac{1}{2}$ of that of the primary, and a mass $7/100$ of the sun's, which if confirmed would make it the least massive body yet recognised outside the solar system. Rigel and α Cygni are suspected to have similar small companions, but the detection of such small masses by changes in the line-of-sight velocity is necessarily a very delicate matter.

Prof. Guthnick has studied the eclipses of σ Cygni photometrically, and states that they last about 3 days, their period of recurrence being 11 days.

OBSERVATIONS OF STARS OF SPECTRUM TYPE Be—Stars of spectrum type B are hot stars, and those which show bright lines in their spectrum are of particular interest because their study will no doubt throw light not only on the conditions of their atmospheres, but may also help to interpret the spectra of new stars and unusual properties of the hydrogen atoms. In the spectra of these stars the hydrogen lines are sometimes very complex, such as was recently described in this column in the case of ϕ Persei as studied at the Norman Lockyer Observatory by Dr. W. J. S. Lockyer. The intensity of the bright hydrogen lines usually decreases from the red to the violet, and as the ordinary photographic spectrum only extends from H β to the ultra-violet, it might occur that while H β and the other lines towards the violet were not bright, the line at H α might appear as a bright line. In fact, most of the so-called bright-line B stars have been discovered because H β or the other hydrogen lines towards the violet were bright.

A recent investigation by Paul W. Merrill, Milton L. Humason, and Cora G. Burwell (*Astrophysical Journal*, vol. 61, p. 389, June), has been devoted to the study of the H α line of B stars, with the result that 90 more bright-line B stars have been discovered. Indeed the discussion brings out the fact that the objective-prism spectrograms have yielded more new bright-line stars than the number previously known within the areas observed. This great increase in the number of these stars has led the authors to inquire into their distribution in the heavens. The result of this study is to show that there is a tendency for them to fall into groups near the centre line of the Milky Way. Four of these groups occupy areas which are also rich in Wolf-Rayet stars. Further, the frequency of bright-line stars in the various spectral divisions has also been examined, and it is found that the spectrum classes B0 to B5 are strongly favoured. The communication includes numerous tables and illustrations, and is a valuable contribution to the study of bright-line stars.

Research Items.

QUATERNARY MAN IN CHINA.—An important addition to our knowledge of the distribution of man in the Pleistocene age is made by the researches of MM. Licent and Teilhard de Chardin, of which a preliminary account is given in Vol. 35, Pts. 3-4 of *L'Anthropologie*. While engaged in examining the quaternary deposits of southern China, they discovered three sites affording evidence of occupation by palæolithic man. The first is situated in the basin of the Choei-tong-k'euou immediately to the south of the Ordos plateau and to the east of the Yellow River, where was found a sharply defined zone of occupation of about 20 m. in length with a deposit of 50 cm. thickness. Upon it was superimposed a bed of loess about 15 m. deep, and above this the gravels of a pre-neolithic river. No human remains were found, but a quantity of fossil bones of *Bos primigenius*, *Rhinoceros tichorhinus*, *Hyæna*, and the tooth of, probably, *Ovis Ammon*. Stone implements were very numerous and of various forms, all being worked on one side only. They were rude in form and rough in workmanship, this being due to the coarse grain of the material employed. At the same time a few scrapers and points showed that, given suitable material such as flint, man here was capable of fine work. Five hearths were discovered in the neighbourhood within an area of about a square kilometre. The third site was found on the Sjarosso-gol, a tributary of the Hoang-ho, and has yielded the complete skull of a rhinoceros, and bones of a species of elephant, *Rhinoceros tichorhinus*, *Equus*, *Cervus*, *Bos primigenius*, *Hyæna spelæa*, etc. The lack of suitable material in this area has affected the character of the stone implements, which, with a few exceptions, are extraordinarily small. Notwithstanding this difference, this site and that at Choei-tong-k'euou may be regarded as contemporary. No traces of industry intermediate in date between this palæolithic culture and the neolithic have been discovered. Although comparison with European cultures is difficult, these sites may be classed as Mousterian or early Aurignacian.

OBSERVATIONS ON A COLLARED FLAGELLATE—Dr. G. Lapage (*Quart. Journ. Micr. Sci.*, June 1925), records observations upon living specimens of the choanoflagellate *Codosiga botrytis* made with the view of ascertaining the nature of the collar and its function as a food-catching apparatus. Study of the organism does not support the view put forward by some previous observers that the collar is a spiral; Dr Lapage holds that it is, as earlier workers stated, a protoplasmic, flexible, retractile, conical membrane, closed on all sides except on its upper free surface. The flagellum which arises in the base of the cup and the currents it produces are carefully described. They cause food to be brought to the collar, by which it is caught and passed down the outside of that structure to be ingested at or below the middle of the body, and not at its upper end and never by the area enclosed by the collar. The method of ingesting the food is fully described. Defæcation invariably occurs from the area enclosed by the collar. There are normally two contractile vacuoles; one of these has been misinterpreted as a "gullet-vacuole" at which food was said to be ingested. Dr. Lapage has not met with any examples which exhibited division, encystment, or conjugation.

RECOVERY FROM PLASMOLYSIS—It has been almost axiomatic amongst botanists to interpret recovery from plasmolysis, when a living cell is immersed in a hypertonic salt solution, as due to the gradual entry of the salt. When the plant cell is immersed in sugar

solution or in solutions of certain salts, no recovery takes place and the sugar or the salt in question is assumed not to penetrate the cell. This interpretation of recovery from plasmolysis will need reconsideration in the light of a recent paper by W. S. Iljin (Studies from the Plant Physiological Laboratory of Charles University, Prague, vol 2, 1924). Iljin points out that the salts which have thus been assumed to penetrate the cell all appear to possess the property of facilitating the hydrolysis of polysaccharides such as starch. The result is the formation of soluble organic compounds within the cell, which raise its osmotic pressure in many cases to a value far higher than would be attained simply as a result of the entry of the salt itself. Salt solutions in which recovery from plasmolysis does not take place also fail to promote hydrolysis of starch. How the monovalent cations and organic anions thus found to be active in hydrolysis produce their effect is not apparent, but Iljin is emphatic that he sees no evidence of any considerable penetration of the cell by these ions.

NORTH-EAST LAND, SPITSBERGEN.—Mr. F. G. Binney gives an account of the Oxford expedition to North-East Land in the *Geographical Journal* for July. This is followed in the August issue by summaries of the scientific results by various members of the expedition. Some additions to the topography and geology have been made. On the east coast a low-lying spit of granitic and metamorphic rock was discovered and named Isis Point. Its position was found to be lat. 79° 42' N., long. 26° 40' E. No islands, such as had previously been reported, were found off the east coast. Soundings showed that the ice cap along this coast is aground and not floating and there is evidence that it is receding at no mean rate. In the interior of North-East Land no features exactly tallying with A. E. Nordenskjöld's "ice-canals" were found but wide crevasses with parallel vertical sides were numerous. They were of great depths and often partly choked with snow, but a definite floor such as Nordenskjöld described was never seen. It is probable, however, that these crevasses were of the same nature as the features discovered by Nordenskjöld.

RAINFALL VARIATIONS OF GREAT BRITAIN.—The *Meteorological Magazine* for June contains an article by Mr. C. E. P. Brooks, of the Meteorological Office, on "Long Period Variations in the Rainfall of Great Britain." The author makes a praiseworthy attempt at grouping past records of rainfall and associating with them the earlier historical records of weather such as storms, floods, and droughts. With the aid of previous work done by G. J. Symons, E. J. Lowe, and Sir Richard Gregory, an approximation is made of the variations of rainfall in Britain since A.D. 1000. Approval is expressed of conclusions obtained by Symons, which is a satisfaction to those who knew Symons' work, and the scrupulous care with which he originated and handled rainfall results. A diagram is given to show the fluctuations of rainfall since A.D. 1000. Prior to 1700 the results are based on generalisations by old chroniclers, and it is only claimed that a rough approximation is obtained; but from 1700 onwards the results are based on actual measurements. There is probably no one who can better claim respect in this research than Mr. Brooks, and the article is of especial interest.

INSTANTANEOUS COLOURED PHOTOGRAPHY.—A method of obtaining coloured photographs by means

of a single very short exposure is described by M. G. A. Rousseau in the *Comptes rendus Acad. Sci. Paris*, July 20. Three films are employed, the first of which has an ordinary slow emulsion, the second is coloured yellow with auramine on the side towards the lens, and pale rose with fuchsine on the other side, and has an emulsion which is sensitive to yellow and green, while the third film is coated with an emulsion which is sensitive to yellow and red. The three films are cemented together along one edge, and pressed together in the camera by means of springs between a thin metal plate and a glass plate. The photograph is taken in the same way as an ordinary one, no screen being required. The blue-violet radiations act on the first film, and are largely absorbed by it. When this is developed it serves as a yellow positive. The radiations which pass through the first film are further filtered by the yellow dye on the outside of the second film, so that no blue-violet radiations pass to the sensitive layer, which is acted on by the yellow and green radiations giving a red positive. Finally, the remaining yellow and green is filtered out by the fuchsine on the back of the second film, so that only the orange group passes to the third film, which gives a positive in which the bright parts correspond to the blue in the object photographed. Monochromes can then be printed in the proper colours from the three films, and when these are superposed, the object photographed is seen with its natural colours.

POLARISATION OF THE ATOM TRUNK—The observed differences between the spectra due to a photo-electron, which circulates in orbits at a distance from the nucleus considerably greater than those of the remaining $n-1$ electrons, and the spectrum calculated from the Balmer formula of hydrogen, have been ascribed to the fact that the photo-electron polarises the atom trunk, so that the configuration of the trunk, to a certain extent, follows the radius vector of the electron in synchronism. The result may be to introduce a term into the law of the force field in which the electron moves, depending on $1/r^3$ or some higher inverse power of r , the distance from the centre of the nucleus. In the *Annalen der Physik* for June, Dr E. Schrodinger calculates the capacity for polarisation, P , of the "neon" trunk for the d terms ($k=3$), and the f terms ($k=4$) of Na I, Mg II, Al III and Si IV, and finds that P is nearly constant in each series when n varies from 3 to 7. A table based on the arc spectra of the alkali metals (inert gas trunks) shows some regularities and some irregularities in the values of P . A remarkable irregularity discovered by Paschen in the Bergmann series of Al II is explained by assuming that, for frequencies a little smaller than the resonance frequency of the trunk, P is large, and for higher frequencies is negative; this depends on the loosening of the structure of the trunk at the resonance frequency. The relations for the arc spectra of the alkaline earths are not very clear, and the explanation given in the case of Al II is to be taken with a certain amount of reserve in consequence.

SULPHUR SESQUIOXIDE.—The *Journal of the Chemical Society* for July 1925 contains an interesting paper by J. R. Partington and I. Vogel on sulphur sesquioxide. There has always been some doubt as to whether the blue substance formed by the interaction of sulphur and sulphur trioxide was a definite compound or a colloidal solution. The present authors have proved that it is a compound, S_2O_3 , analogous to the well-known $SSeO_3$ and $STeO_3$, which are formed in a similar way. The properties of the oxide are described as well as futile attempts to isolate sulphur monoxide.

NICKEL.—Dr M. Cook contributes an interesting article on nickel to the *Chemical Age* for August 1. Copper-nickel alloy was in use so early as 235 B.C., but nickel itself was not isolated until 1751, by Cronstedt. The chief sources are the ores of Sudbury (Canada) and New Caledonia. Pure nickel cannot, in general, be worked, it is made malleable by the addition of about 0.1 per cent. of magnesium, a discovery due to Fleitmann. The function of the magnesium is to break down the nickel sulphide which occurs as films around the nickel crystals and so renders the metal brittle. Magnesium sulphide, insoluble in molten nickel, is produced and occurs disseminated throughout the solid metal. The influence of various impurities on the properties of the metal is discussed. The mechanical properties of the metal are listed and the numerous methods of working are briefly described. Some of the toughest non-ferrous alloys known contain nickel. The metal is finding numerous uses, and more than seventy countries utilise it or its alloys for coinage purposes.

DIAGNOSING POTENTIAL OPTICAL ACTIVITY.—An important article on the detection of potential optical activity, by Prof. John Read and Miss A. M. M'Math, appears in the July number of the *Journal of the Chemical Society*. Until 1914 no one-carbon molecule had been obtained in optically active modifications. In that year, however, Sir William Pope and Prof. Read succeeded in resolving chloro-iodomethanesulphonic acid, and found that the active forms showed pronounced optical activity. This rendered the lack of success which was experienced in attempting to resolve chloro-bromomethanesulphonic acid all the more remarkable. Prof. Read and Miss M'Math have now found that by salt-formation between this acid and *l*-hydroxyhydrindamine in organic solvents, and subsequent recrystallisation from acetone containing a little methyl alcohol, two salts are produced which differ widely in crystalline form and solubility. Their specific rotatory powers are different in organic solvents, but identical in water, and both salts show a remarkable mutarotation in certain organic solvents. The authors adduce evidence to show that these salts are to be represented as *l*B*l*A and *l*B*d**l*A respectively, and that in pure dry acetone either of them rapidly attains an equilibrium of the following kind:

81 per cent 19 per cent

The diastereoisomeric salts thus exist in dynamic equilibrium, and the whole of the original acid may be removed in the form of the less soluble salt, *l*B*l*A. This salt changes instantaneously into the partial racemate, *l*B*d**l*A, in contact with water, which apparently exerts a potent catalytic racemising effect even when added in small amounts to solutions of *l*B*l*A in organic solvents. The authors advance the view that asymmetric carbon compounds of simple molecular constitution are as a rule exceedingly susceptible to racemisation, owing to the mobility of the groups attached to the asymmetric atom. Easy racemisation involves the complementary possibility of easy optical stabilisation under an appropriate asymmetric influence, and the new method of diagnosing potential optical activity is based upon this principle. The authors "anticipate that asymmetric compounds containing two carbon atoms in the molecule will also display phenomena of the kind now described, and thus lend themselves to preparation for the first time in optically pure combinations by treatment with optically active bases in organic solvents. Through a systematic application of the method to asymmetric compounds of simple molecular constitution, it is hoped to gather much new information respecting the comparative mobility of groups in systems of the kind."

Developments in Gas Calorimetry.

By Dr. J. S. G. THOMAS.

SECTION 5 of the Gas Regulation Act, 1920, requires that, in certain cases, apparatus for testing towns' gas "shall include a calorimeter for the production of a continuous record of the calorific value of the gas which is being supplied." During the interim period of development of a suitable and satisfactory recorder, the statutory testing of the calorific power of gas has, in accordance with the specification of the Gas Referees, been done in practically all cases by determinations of calorific power made at specified periods with a Boys calorimeter. The cost and elaborate procedure at present necessitated by this method of testing have become a serious burden,

FIG. 1.

particularly in small country places, and with the view of reducing these difficulties Prof. C. V. Boys has designed a simple equipment which he described at the meeting of the Institution of Gas Engineers on June 10 last. The apparatus is illustrated in Fig. 1.

Water required for the test is contained in an upper reservoir, and after passing through the calorimeter is received in the tank or lower reservoir below the table, whence it may be restored to the upper reservoir by operation of the handle of the pump, the water entering at the bottom of the upper reservoir, so that by continuing the pumping operation air is forced into the water, the consequent stirring ensuring uniformity of temperature. The customary overflow funnel system for determining the water rate through the calorimeter has been replaced by a float control, resembling a carburettor in design. Water passes from the calorimeter by a swivel outlet tube moving between stops, so that the water may either flow to

the lower reservoir or be collected in a measuring flask during the actual test. Prof. Boys has, very reluctantly, been obliged to abandon the use of "onazote" which he employed in the construction of his "Block" calorimeter as a water-containing and insulating material, and has reverted to a construction very similar to that employed in his recording calorimeter (NATURE, August 19, 1922, p. 251) for the water circulation within the present "Box" calorimeter.

Gas to be tested is efficiently governed and passes through a micrometer tap to a Boys "Bell Meter," and thence to a burner consisting of a narrow inner tube terminating within a plain silica tube open above and below. There are no moving gas connexions, and as the gas is somewhat aerated before combustion it is possible to burn as much as one cubic foot per hour without risk of imperfect combustion. Readings of inlet and outlet temperatures of the water passing through the calorimeter may be taken after the burner has been alight about 15 minutes.

The Boys "Bell Meter," shown also in Fig. 2, incorporates some of the essential features of the meter employed in Prof. Boys's recording calorimeter

FIG. 2.—Boys "Bell Meter."

(NATURE, *loc. cit.*). A celluloid or nickel drum is graduated along its circumference and is supported on an axle moving in bearings in water, no stuffing box being employed. A buoyancy chamber supports most of the weight of the drum and forms a solid floor to the major part of each compartment of the drum when gas is trapped within it. The water level is determined by a submerged needle. Water may be added to or run off from the meter by means of the fitting seen on the left of Fig. 2. By these means the tiresome operation of meter-proving becomes unnecessary.

In the case more especially of small gas undertakings, where financial considerations unduly limit the number of tests of calorific power of the gas supplied, it is difficult to ascertain the mean value of the gas supplied over the statutory period. The consequence of the present procedure is that small gasworks, in order to prevent an adverse report, have to provide gas which on the whole is of higher calorific value than that declared. Prof. Boys suggests tentatively that in the case of such undertakings the gas supply over any period should be sampled by being slowly and continuously drawn into a small holder in the testing place, maintained if necessary at a uniform temperature, and that the sample so collected should be tested by the Gas Examiner. Owing to the small rate of gas flow and the short time taken, less than half a cubic foot of gas is sufficient for a test. In an apparatus designed by Prof. Boys for such sampling,

the gas lifts a balanced bell at a rate controlled by a clock. A chain from the bell to a balance weight made as a sprocket chain passes over a sprocket wheel connected by a clutch to a clock-turned axle, the clutch acting in such a direction that the bell cannot rise faster than the clock permits, whilst it is always free to descend when weighted. This system of clock control of sampling lends itself readily to any agreed

scheme of variation of the rate of sampling which may be considered equitable and in accordance with the variation of the rate of gas supply to the district during the hours of day and night. Should experience show that there is no loss of quality due to sampling and storage, the method would ensure one of the most important objects of the Gas Regulation Act being attained.

The Transmission of Excitation in Plants.

THE question of the mechanism of transmission of excitation in plants has been for some time under discussion in the columns of NATURE. The most recent contribution to the discussion is a paper by Sir J. C. Bose, entitled "Physiological and Anatomical Investigations on *Mimosa pudica*," published on August 1 in the Proceedings of the Royal Society (No. B 690, vol. 98).

The first section of the paper is devoted to the vexed question of the nature of the process of transmission. It has been suggested by Prof. Ricca that it is purely physical; a stimulating substance (hormone), produced at the seat of stimulation, is conveyed to the motile leaves by means of the transpiration-current in the vessels of the wood. Another suggestion, that of Mr. R. Snow, is to the effect that whilst Prof. Ricca's explanation may apply to transmission through relatively long distances in the stem, it does not apply to the petiole, where the excitation seems to travel from cell to cell. Sir J. C. Bose arrives at the conclusion that the process of transmission is the same in both stem and petiole; that it is not physical in either, but is wholly physiological, a wave of protoplasmic excitation, just as it is in the nerve of the animal.

The experimental evidence upon which his conclusion is based is both negative and positive. The author failed, after many attempts, to repeat the experiment upon which the transpiration-current theory depends, that is, to observe the transmission of excitation from one piece of stem to another connected with it by a glass tube containing water. Further, if the physical theory be true, it is obvious that the velocity of the transmission of excitation and that of the transpiration-current must be the same; but it was found that the former is far greater than the latter.

On the positive side, Sir J. C. Bose observed that transmission in *Mimosa* was affected experimentally in the manner well known in animal nerve. For

example, in both the velocity of transmission is increased by rise of temperature and by desiccation. Again, on passing a moderately strong electric current (6 volts) through a length of the stem, the effect at "make" of the current was observed, by the fall of adjacent leaves in one direction, to be stimulation at the cathode; on breaking the current, stimulation was induced at the anode, evidenced by the fall of leaves in the opposite direction. It was further demonstrated that transmission is arrested by an electrotonic block; that is, excitation cannot travel along a tissue through which a constant electric current is being maintained. These results, obtained equally with stem and petiole, go to prove that excitation is transmitted in the plant in essentially the same manner as it is in the nerve of the animal.

The remaining sections of the paper deal mainly with anatomical details. The conclusion is reached that the phloem is the tissue that conducts excitation; not the sieve-tubes, but the elongated tubular cells of which the phloem mainly consists. Moreover, evidence is adduced that a strand of these tubular cells occurs also on the inner surface of each xylem-bundle, and this strand is termed the "internal phloem." The results of anatomical observation agree with those of physiological investigation by means of the electric probe. When the probe was inserted gradually into the petiole, maximum negative galvanometric deflexion was manifested when it penetrated the external phloem and again when it reached the internal phloem.

The paper concludes with a comparative study of the pulvinus, from which it appears that the more excitable the pulvinus the more deeply does the protoplasm of its contractile cells stain with safranin; it also reduces osmic acid, indicating the presence of a readily oxidisable substance, not a fat or a lipid, which is probably concerned in developing the energy required for the active contraction of the organ.

Earthquake Investigation in the United States.

AS already mentioned in NATURE of April 25, p. 615, an act of the United States Congress was approved early this year, enacting "that the Coast and Geodetic Survey is hereby authorised to make investigations and reports in seismology, including such investigations as have been heretofore performed by the Weather Bureau." The reasons for the change and the work that it is hoped to accomplish are given in an excellent popular account (U.S. Coast and Geodetic Survey, Serial No. 304, price 10 cents) by Mr. E. Lester Jones, the director of the Survey.

In 1899, the Coast and Geodetic Survey developed a plan for the magnetic survey of the United States, and five observatories were established in places that proved to be admirably adapted for earthquake observations. Of these places—Porto Rico, Maryland, Arizona, south-east Alaska and Hawaii—three are in major earthquake zones and one near

such a zone. As in other places, it was found that the magnetic instruments recorded certain kinds of earthquake waves, and they were supplemented by seismographs which have been in action for more than twenty years. In 1906, after the Californian earthquake, the Weather Bureau installed seismographs at Chicago, Washington and Northfield (Vt.), but, after a time, it was found that seismological investigation, and especially the instrumental part, did not fit in well with the work of the Weather Bureau, nor did the Coast and Geodetic Survey feel justified in attending to seismographs merely as an adjunct to its magnetic work. Accordingly, by agreement of the Secretaries of Agriculture and Commerce, Congress was asked to enact the legislation referred to above.

In several ways, the ordinary work of the Coast and Geodetic Survey is adapted for earthquake investigations. The routine of operating magnetic

instruments, with the necessary attention to details which such precise instruments require, gives the observers the qualifications needed to get the best results from high-grade seismographs. The Survey maintains tidal stations at numerous points along the coast with continuous record by automatic gauges. Most important of all is the fact that the changes in the horizontal or vertical position of places in the central area of an earthquake can be determined only by precise triangulation and levelling. Such work by the Coast and Geodetic Survey has been in progress for three years in California, for it is understood that not only have changes occurring at the time of earthquakes to be considered, but also movements of large areas as a whole between earthquakes.

C. D.

University and Educational Intelligence.

A SUMMARY of important State Laws relating to education enacted in 1922 and 1923 has been published by the United States Bureau of Education in Bulletin 1925, No. 2. In the year 1923, laws were passed in twenty-two States prescribing instruction in the public schools in the constitution of the United States, the duties of citizenship, or "Americanism," which is defined (North Carolina) as including (a) respect for law and order, (b) character and ideals of the founders of the country, (c) duties of citizenship, (d) respect for the national anthem and the flag, (e) a standard of good-government, (f) constitution of N. Carolina, (g) constitution of the United States. In Florida, teachers and professors in State institutions were forbidden to teach atheism or agnosticism or to teach as true Darwinism or any other hypothesis that links man in blood relationship to any other form of life.

THE London County Council has again arranged numerous lectures for teachers during the winter, and a descriptive handbook has been prepared (The County Hall, Westminster Bridge, S.E.1.). The lectures scheme is now self-supporting, and last year's attendance approached 14,000. Any person engaged in teaching in London or Middlesex is eligible for admission at fees which average less than 1s a lecture; out-county teachers are admitted at fees 50 per cent higher. Among the lectures which will interest readers of NATURE are the following.—Special single lectures by Prof. J. Arthur Thomson on "Visualising in Nature Study," by Sir William Bragg on "Quartz," by Sir Sefton Branner on "Aviation in the British Empire," Dr. A. S. Russell on "Radio-activity," Prof. Leonard E. Hill on "Sunlight and Open-Air Classes," and by Mr. Richard Kerton on "Wild Life round London." Courses will be given by Prof. T. P. Nunn on science for the elementary school, by Dr. L. F. Bates on modern theories of magnetism, by Mr. J. W. Bispham on science-teaching in junior technical schools, by Prof. Cyril Burt on mental tests, and on experimental psychology and its bearing upon education. In mathematics there will be three courses dealing with the teaching of mathematics of different grades, while Prof. H. Levy is giving a course on the work of the mathematical laboratory. Geography is represented by courses on physical, regional and historical geography, on the teaching of local geography and on practical work in geography. These lectures are valuable in that they enable teachers to keep in touch with modern developments in their respective subjects.

THE City and Guilds of London Institute has issued as an addition to its report for 1924 (the

forty-fifth annual report since the incorporation of the Institute) a report to the University of London by the University's Visitor, Sir Alfred Ewing, on the research, teaching, and equipment of the City and Guilds (Engineering) College. The Visitor found much to admire and very little to criticise. His observations relate to matters of such fundamental importance, and they are supported by lucid statements of principles so generally applicable, that they deserve attentive consideration by other engineering schools. Referring to the danger, to which all engineering schools are exposed, of overloading the course with a study of technological method and detail which takes up the time and attention that should be given to matters which are far more educative and, in the long run, of greater professional importance, Sir Alfred Ewing remarks that it "tends to become more acute where a school is divided into departments which may tempt a student to specialise prematurely, and where in each department there is a lavish equipment of large-scale engineering plant." He adds, however, that the course at the City and Guilds College, where the laboratories are extraordinarily spacious and splendidly equipped, is, on the whole, well balanced. Among the novel and interesting features of the laboratory work are testing machines of a new type designed by Prof. Dalby. A large section of the laboratory is not in use at present on account of the difficulty of paying rates on it. The technological examinations conducted by the Institute in Great Britain and Ireland were held at 297 centres, and the number of candidates examined was 8578. In addition, 1326 candidates were examined in the Dominions Overseas (chiefly New Zealand) and India.

THE League of Nations (Information Section) sends us a report on the "Instruction of Children and Youth in the Existence and Aims of the League" which is to be submitted to the Sixth Assembly opening in Geneva on September 7. The report shows that the League's propaganda has led to a vast amount of activity on the part of government departments, national associations of teachers, and other national and international organisations in the preparation of special pamphlets and magazine articles, the provision of special lectures and courses of instruction, the organisation of conferences, exhibitions, schemes for awarding special diplomas and badges, inter-scholar correspondence, exchange of students and international visits, and obtaining travelling facilities and collective passports. The Sixth Assembly is to consider, *inter alia*, a proposal that the League's Committee on Intellectual Co-operation should invite all professors and teachers to collaborate by preparing and distributing to all scholastic institutions literature instructing the young in the aims of the League. The effects of all these activities in different countries will depend to a great extent on the place already held in the national system of education by instruction in the duties of citizenship and practical exercises in those duties. Where, as in the United States, these are commonly recognised as an essential part of primary education, the attempt to establish a new loyalty to the ideals of the League may find a safe foundation of patriotism on which to work, but when this foundation is lacking the results may be unfortunate. In Great Britain, at any rate, it may well be asked whether the teaching of loyalty to that older league of nations known as the British Empire should not take precedence. "The internationalism that denies the worth of patriotic preference," says Wickham Steed in the preface to his reminiscences, "is as debilitating as is unqualified scepticism in regard to philosophical or religious belief."

Early Science at Oxford.

September 9, 1684. A letter from Mr. Creech, dated from Worcester, September the 4th, was read; it gave an account of a Woman in Worcester, who, for these twenty years last past, has every Sunday had a Convulsion Fit, and at no time else, unless she puts both her feet over her threshold; which if she does, a fit certainly seizes her; the case of this woman is drawn up by ye learned Dr. Cole, Physitian at Worcester, and was communicated to severall of the physitians in Oxford about a year and a half since.

Mr. Francis Davenport's account of the Tides at Tunquin and Mr. Halley's Theory of those Tides, were read, and will be printed very suddenly.

Dr. Plot communicated an Instrument made by Mr. Bard of Fretwell, for ye better æstimating ye increase, and decrease, of ye weight of oil of vitriol exposed to ye open air: ye Doctor promises us to make use of it, and give ye Society an account of ye success

Dr. Plot also communicated an account of ye weather here at Oxon: during ye last month; and an abstract of a letter from the Reverend Dr. Thomas Smith, now at London, who says, that a Naturall History of Scotland is lately printed at Edinborough by Sir Robert Sibbald.

The Doctor further communicated to the Society that, in a visit made by himself to ye men of Siam lately come into England, he received from them a present of a black lead pen of their country, and a nut whose kernell is call'd Areka, which has a smart aromattick tast, and is said to be purgative

He understood from them, that their alphabet, and numerall figures, were ye same with those of ye Indians.

Dr. Smith shewing himself very ready to oblige ye Society, by proposing to those men of Siam any quæries which shall be sent him hence, it was offered by Mr. Bernard, that ye Doctor be desired to discourse with them on ye severall heads of Dr. Plot's sheet of enquiries

There being some discourse concerning Barometers, particularly it being affirmed, That a candle placed near ye upper and empty part of ye Tube will make ye quicksilver descend; it was proposed by Mr. Bernard, that tryall be made, whither spirit of hartshorn, applied to the top of ye Tube, will cause ye quicksilver to ascend?

Mr. President proposed that enquiry be made whether the quicksilver arises and falls in old barometers, to as many degrees, as it did in ye same barometers, when they were new? In one, which he for many years made use of, he has found it does not.

Dr. Plot presented ye Society with a peece of heavy wood from Jamaica, called *Kicongo*; 'tis of a smell like *Enula Campana*. Some Experiments will be tried on it very suddenly; and an account of them brought in to the Society.

The Doctor, having finished his discourse *de Origine Fontium*, was, at this meeting, desired by ye Society, to communicate it to them, and begin reading it the next week

The Society then tooke into consideration the enlarging of their Correspondence; for ye effecting of which, they concluded, that some attempts be made for ye settling a Correspondence in Scotland, in like manner, as it is now carried on between ye Royall Society, and that of Dublin, and this of Oxford; in order whereunto, it was ye most humble request of this Society to Mr. President to take on him ye trouble of writing to the Heads of ye Universtys in Scotland, concerning this affair.

Societies and Academies.

LONDON.

Institute of Metals (Autumn Meeting, Glasgow), September 2.—J. H. Andrew and Robert Hay. Colloidal separations in alloys. The β constituent may break down into colloidal α and colloidal γ , and upon submitting these to an electrical current, the colloid is destroyed and the crystalline phase begins to make its appearance. The ageing of duralumin may be due to the deposition of the magnesium compound in the colloidal form, when the increase in hardness would be due rather to the fineness of state of division of the separating phase than to its specific properties.—John S. Brown: The influence of the time factor on tensile tests conducted at elevated temperatures.

With non-ferrous alloys there is a critical temperature condition, above which the rate of application of the load has an important influence on the observed strength. This time factor tends to lose its effect when the rate of loading is kept below 1 ton per sq. in. per day, and this value is consequently put forward as of basic importance in such investigations.

—R. B. Deeley: Zinc-cadmium alloys. A note on their shear strengths as solders. A substitute for brazing spelter was required for the motor-cycle industry. The working temperature of the substitute solder had to be below that likely to promote coarse crystallisation of the hard-drawn steel tubing of the frame, and the melting point had to be sufficiently above the enamel stoving temperature (about 180° C) for joints made with the alloy not to fail during enamelling. Zinc-cadmium alloys in pure shear show the strongest alloy to be near the eutectic composition. This alloy is considerably stronger than tinman's solder, 8 tons/sq. in. compared with 4 tons/sq. in.—J. W. Donaldson: Thermal conductivities of industrial non-ferrous alloys. The thermal conductivities of 70:30 brass, high tensile brass or manganese bronze, Admiralty gunmetal, ordinary gunmetal, bearing phosphor bronze, white bearing metal, and monel metal are low, ranging from 0.067 for monel metal to 0.242 for 70:30 brass. Increasing the temperature increases the conductivities. The alloys of tin and copper have a lower conductivity than those of zinc and copper, while nickel lowers considerably the conductivity of an alloy containing it.—Marie L. V. Gayler: On the constitution of zinc-copper alloys containing 45 to 65 per cent. of copper. In an equilibrium diagram, no change in microstructure of alloys consisting wholly of the β constituent could be detected.

—J. L. Houghton and W. T. Griffiths: The β transformations in copper-zinc alloys. The change of resistivity with temperature was determined for some alloys containing from 46 to 63 per cent. copper. Above 55 per cent. copper the β -transformation temperature is 453° C., between 55 per cent. and 51 per cent. copper it takes place at temperatures rising from 453° C. to 470° C., with less than 51 per cent. copper the transformation temperature is 470° C. These data are opposed to the theory that this is a eutectoid transformation. The specific resistances at room temperatures were also measured after annealing just above the transformation point. The resistance falls rapidly as the copper decreases from 61 per cent. to 53.5 per cent., and less rapidly to about the 50 per cent. copper alloy; it rises steeply from this point with further decrease of copper content. Thus the two boundaries of the field at room temperature occur at 50.0 and 53.5 per cent. of copper.—C. H. M. Jenkins: The physical properties of the copper-cadmium alloys rich in cadmium. Alloys containing up to 5 per cent. of copper in the

cast, rolled and annealed states, were used. The effect of even a small addition of copper to cadmium is to cause the formation of a second constituent CuCd_2 , this increases the tensile strength and Brinell hardness and prevents the grain growth of cadmium on annealing. Additions of more than 3 per cent. of copper do not materially improve the mechanical properties of cadmium owing to the presence of too large a proportion of the brittle compound.

PARIS.

Academy of Sciences, July 20.—A. Haller and R. Cornubert: The constitution of the dimethylcyclopentanone and the dimethylcyclohexanone obtained by alkylation by means of the sodium amide method.—Nicolas Kryloff: A method based on the principle of the minimum, for the approximate integration of differential equations.—R. A. Fisher: The solution of the integral equation of V. Romanovsky.—W. Stepanoff: Some generalisations of nearly periodic functions.—Rolf Nevanlinna: A theorem of unicity relative to uniform functions in the neighbourhood of an essential singular point.—N. Lusin: The use of the diagonal of Cantor.—R. Roudaire-Miégevillé: A new grapho-mechanical determination of systems of real or imaginary solutions of algebraical equations.—J. Seigle: Tests of mild steel by combined stresses.—Marcel Peschard: The magnetisation of ferro-nickels (paramagnetic properties).—G. Athanasiu: The sensibility of actinometers with electrodes coated with silver iodide and copper oxide.—G. Bruhat and M. Pauthenier: A theoretical study of $320\text{ m}\mu$ of carbon disulphide.—R. de Malleman: The calculation of rotatory power starting with the molecular structure.—S. Pina de Rubies: The arc spectrum of scandium. The scandia was extracted by G. and P. Urbain from Madagascan thortveitite, transformed into the acetyl-acetonate and the latter purified by repeated sublimations in a vacuum at 190°C , followed by recrystallisation from absolute alcohol. A table of wave-lengths and intensities is given.—Gabriel A. Rousseau: Method for instantaneous photography in colour. Three films are superposed: the first receives a slow ordinary emulsion, the second an emulsion sensitive to the yellow and green, and the third an emulsion sensitive to the yellow and red. Details of the preparation of the sensitised films are given. The photograph is taken without a screen, working as with an ordinary plate.—Adolphe Lepape: The radioactivity of some cold springs in the Bagnères-de-Luchon region and on its origin.—Mlle. Germaine Cauquil: Study on viscosity and surface tension during esterification.—Pariselle and Laude: The magnesia carried down by alumina in ammoniacal media. The presence of a large excess of ammonium chloride prevents co-precipitation of magnesia with aluminium hydroxide.—Pierre Bedos: A new racemic menthone and the two corresponding stereoisomeric menthols.—R. Locquin and R. Heilmann: The decomposition of the pyrazolines by spontaneous oxidation. The spontaneous oxidation of pyrazolines by air is complex and gives either a saturated or an unsaturated ketone, together with basic substances of high boiling point, so far not identified.—E. E. Blaise and Mlle. M. Montagne: The transformation of the dialkylcyclohexenones into dialkylbenzenes. Methyl-ethylcyclohexenone heated in a sealed tube on the water bath with a saturated aqueous solution of hydrobromic acid gives *o*-methylethylbenzene. The reaction appears to be of a new type.—I. Pouget and D. Chouchak: The radioactive mineral waters of Guergour, Algeria.—Mlle. H. Popovici: The formation of essential oils.—Raoul Combes: Does light exert a direct action on the decomposition of chlorophyll in

leaves in the autumn? The results of the experiments described are not in agreement with Wiesner's hypothesis, and light does not appear to be a direct cause of the disappearance of chlorophyll from leaves in the autumn.—André Mayer and L. Plantefol: The equilibrium of the cellular constituents and form of oxidations of the cell. Imbibition and respiratory types in reviviscent plants.—H. Colin and A. Grand-sire: The mineralisation of green leaves and of chlorotic leaves.—P. R. Bohn: The presence of crystals of calcium oxalate at the surface of certain Caryophyllaceæ.—Kühner: The development of *Lentinus tigrinus*.—Emile Saillard: The method of Clerget. Coefficients of inversion. Inversion at the ordinary temperature for 28 hours, or at 70°C (11 minutes) gave the same results. The inversion coefficient varies slightly with the concentration of the saccharose: figures are given for coefficients of solutions from 4 to 16 per cent. of saccharose.—Ch. Brioux and J. Pien: The use of the quinhydrone electrode for the determination of the p_H of soils. This method is advantageous from the point of view of rapidity and simplicity, but there are divergences between the results obtained by the quinhydrone and hydrogen electrodes at present unexplained.—M. and Mme A. Chauchard: The law of excitability of the electrical apparatus of *Torpedo marmorata*.—A. Rochon-Duvigneaud, E. Bourdelle, and J. Dubar: An attempt at the determination of the anatomical binocular visual field of the horse.—F. Viès and A. de Coulon: Relations between the experimental displacement of the muscular isoelectric points and the evolution of grafted tumours.—L. Hugounenq and J. Loiseleur: The superposition of the phenomena of dissociation and elective adsorption in the proteolytic diastases.—E. Kayser and H. Delaval: Radioactivity, nitrogen fixers and alcoholic yeasts. In an earlier communication it was proved that the addition of a radioactive mineral to the ordinary nutritive medium stimulated the action of Azobacter, and the increase varied with the strain of the organism. These results are now supplemented by varying the proportion of the radioactive mineral, by ascertaining the influence of repeated use, and by determining the ratios between sugar used up and nitrogen combined. The effect of the radioactive mineral on alcoholic fermentation has also been studied.—Jean Bathellier: The period of the determination of the castes in *Eutermes matangensis*.—Ch. Champy: The disharmony of the secondary sexual characters and the proportionality of the sexual glands in insects.—G. Ramon: The production of antitoxins.—F. Diénert: Contribution to the study of activated sludge.—Georges Bourguignon: The physio-pathological signification of Babinski's test.—C. Levaditi, A. Girard, and S. Nicolau: The treponemical action of gold and platinum.—Georges Truffaut and N. Bessonoff: The predominance of the activity of anaerobic nitrogen fixers in the soil.

CALCUTTA.

Asiatic Society of Bengal, August 3.—H. L. Chhibber: Microscopic study of the old copper slags at Amba Mata and Kumbaria, Danta State, N. Gujarat, India. The sites are two old metallurgical centres more than six hundred years old. The slags are mostly the remains of low grade minerals of the oxidised zone; no great depth below the surface was worked.—N. G. Mazumdar: Dacca image inscription of the reign of Lakshmanasena. Iconographically this is an important image, as representing an otherwise unknown type of Chandī.—B. S. Guha: Preliminary report on the anthropometry of the Khasis. Measurements were made of inhabitants of Cherapunji and neighbouring villages. Special attention was given to the measurements of

the face; there is difficulty in determining the shade of colour of the skin of brown people.—Hem Chandra Das-Gupta: Palaeontological notes on the Panchet beds at Deoli, near Asansol. Descriptions of three specimens: (1) the carapace of a brachyurous crab (?); (2) a stegocephalian cranium; (3) a reptilian coracoid. The second specimen is tentatively identified as belonging to *Pachygona incurvata*, Huxley, the third specimen, similarly, to *Epicampodon* (*Ankistrodon*) *indicum*, Huxley. The first specimen differs from the only two described genera of Triassic brachyurous crabs.—Sukumar Sen: Notes on the employ of the cases in the Kāṭhaka-saṃhitā. An analysis of the use of the cases as exhibited in Leopold von Schroeder's edition, published from 1900 to 1910, shows a marked difference in language and idiom as compared with other Vedic prose texts.

MELBOURNE.

Royal Society of Victoria, July 16.—Gerald F. Hill: Termites from the Ellice Group. The only species of termite hitherto recorded from these islands has been confused with an American species until recently supposed to have been introduced into Hawaii. The species is identical, however, with an imperfectly known Samoan insect—*Calotermes samoanus* Holmgr—and not with any described Hawaiian or American form. *Proterhinotermes inopinatus* Silv., hitherto known only from Samoa, is now recorded from the Ellice Group. Both species are destructive to coconut palms.—C. E. Eddy: The *L* absorption limits of lutecium, ytterbium, erbium, and terbium. The *L* series critical absorption wave-lengths were measured relative to tungsten *L* lines as standards. A metal X-ray tube, with a thin window, and capable of being operated at 30 kilovolts and 30 milliamperes, was constructed, and used in conjunction with a low pressure spectrometer. The values of the critical absorption wave-lengths were as follows:

	<i>L_I</i>	<i>L_{II}</i>	<i>L_{III}</i>
Lutecium . . .	1136.21 X.U.	1194.0 X.U.	1337.5 X.U.
Ytterbium . . .	1176.4	1238.14	1382.64
Erbium . . .	1265.5	1335.60	1479.19
Terbium . . .	1417.0	1499.4	1644.2

—W. J. Harris: Victorian graptolites (new series), Pt. 2. Four graptolites are described, three being new species, and one of these representative of a new family. Atopograptidae (*fam. nov.*)—a biserial form with thecae with extroverted apertures; represented by *A. woodwardi*, *nov.*, from Bendigo East. *Didymograptus nodosus*, *sp. nov.*, and *Cardiograptus crawfordi*, *sp. nov.*, from Bendigo East and Gisborne (Victoria). These three species are from Upper Darriwil beds, near the top of the Lower Ordovician.—W. M. Bale: Further notes on Australian hydroids, V. This paper describes *Sertularia nana* and *S. gracillima* new species, and gives a detailed account of *S. furcata* Trask, a common Californian species recorded doubtfully as Australian. A *Sertularella*, originally referred to *S. polyzonias*, is now described as *S. peregrina* n. sp. It is most nearly related to *S. mediterranea* Hartlaub. *Plumularia delicatula* Bale is given a new name—*P. wilsoni*—on account of the priority of *P. delicatula* Busk (an Aglaophenia). A variety of *Aglaophenia divaricata* Busk, formerly referred doubtfully to *A. acanthocarpa* Allman, is named var. *briggsi*.—Irene Crospin: The geology of Green Gully, Keilor, with special reference to the fossiliferous deposits. Green Gully is near the Keilor township, ten miles from Melbourne. The rocks consist of a succession

of Cainozoic sediments overlying the older basalt which rests on the Silurian bed-rock. The lowest of these Cainozoic sediments is a moderately deep-water limestone which passes into a fossiliferous ferruginous rock, both of which are of Miocene (Janjukian) age. The limestone is characterised by a rich growth of calcareous alga (*Lithothamnium*) and by the abundance of the discoidal tests of several species of *Lepidocyclina*. The ferruginous bed contains a large assemblage of molluscan fossils, mainly in the form of casts, as well as some corals, which show close relationship with the Janjukian fauna of Table Cape, Tasmania, some species being restricted to the two localities.—Frederick Chapman: Geological notes on Neumerella and the section from Bairnsdale to Orbost. Fossils are of Miocene (Janjukian) age and were collected at Neumerella during the construction of the Bairnsdale to Orbost line. 150 species of fossils are recorded and notable additions made to the lists of fossil fishes, ostracoda, mollusca, polyzoa, and foraminifera. The fossil bands are seen in the cuttings, with remains of cetaceans and sharks' teeth; there are intercalated marly limestone layers, and evidence of local crumpling and faulting in the Janjukian. Large volutes and Nautilus frequently occur in the yellow marls as casts, and many are encrusted with a crystalline coating of calcite, probably representing the dissolved shell.

ROME.

Royal Academy of the Lincei, June 21.—B. Grassi: Contribution to the study of the biology of *Anopheles superpictus*.—B. Longo and A. Cesaris-Demel: The possibility of anaphylactic sensitisation in vegetable organisms.—S. Saks: Integration of the polynomials of Stieltjes.—Bruno Finzi: The motion of the boomerang.—Luigi Carnera: The new Washington catalogue of fundamental stars and the Berlin catalogue of circumpolar stars.—D. Pacini: Observations on the vertical air-earth current.—E. Fermi and F. Rasetti: Effect of an alternating magnetic field on the polarisation of resonance light.—E. Persico: Amplitude of the oscillations produced by a three-electrode lamp.—L. de Caro: Surface tensions of gelatin solutions of different hydrogen-ion concentrations.—E. Clerici: The diffusion of certain microscopic organisms of the rocks accompanying the Roman volcanic tufas.—Silvio Ranzi: The organ of sense derived from the first epibranchial placoid of Selacei.

The Worth of Knowledge.

*O fret not after knowledge !—I have none,
And yet my song comes native with the warmth.
O fret not after knowledge !—I have none,
And yet the Evening listens.*

KEATS.

IN the course of his presidential address to the Education Section of the British Association at the recent Southampton meeting, Mr. W. W. Vaughan, headmaster of Rugby School, remarked that an agricultural labourer who had left school at thirteen years of age is often a better-educated man, in the best sense of knowledge, than a city clerk or other black-coated worker who had passed through a secondary school course before entering office life. Those who are familiar with the countryside and farm labourers know that much truth is contained in Mr. Vaughan's observation, but they know also that it is a dangerous doctrine to preach because of the excuse it gives to farmers and parents to secure the release of children from school at the earliest possible age in order to put them at work in the field. It is easy to suggest that a child who leaves school for outdoor work at ten or twelve years of age may be learning more than he would in a village classroom, but this is the kind of reasoning that leads to the exploitation of child-labour; and, in Great Britain at any rate, the State has rightly decided that every child without exception, whether in country or town, must now remain at school until at least the age of fourteen years has been reached.

There are, of course, many social reasons for this necessary condition, and among them is the value of discipline. Knowledge itself, especially that often contemptuously called "book-learning," may, as Keats expressed in the lines from his sonnet on "The Thrush," quoted above, be of little actual worth as a means of gaining or giving delight to life, yet, like the gift of mercy, it can be twice blessed if rightly used. There is one joy in seeking after knowledge and another in arousing interest in others in the beauty and promise of the new world revealed. What is worth having is worth sharing, and it is because of this conviction that we continually urge support and encouragement to effort made to create and foster wide interest in scientific achievement.

This is one of the objects of the British Association, and we believe that the annual meetings do much to fulfil their purpose in this respect through the publication in the newspapers of summaries of the presidential addresses, lectures and selected papers. It is, however, in no captious spirit that we suggest that much more remains to be done if the service of science in modern life is to be understood through the meetings

of the Association. In the first place, there should be no misapprehension as to the constitutions of the audiences for which the president's address and the addresses of the sectional presidents are intended. Members of the lay public are invited to join the Association, but the presidential addresses are almost invariably unintelligible to them; and so are most of the papers. There are no doubt people like the lady who said she did not understand a scientific lecture she had attended, yet she liked the sound of it, but it is scarcely the function of the Association to titillate the ears of passive listeners.

We are of the opinion, however, that the addresses of the president and of the sectional presidents are better read than heard, and on this account we are glad that they are again available in volume form.¹ The first part of Prof. Lamb's presidential address deals with the absorbing topic of the nature and purpose of science in general, and we hope that it will be widely read and discussed, for such remarks, so admirable in form and substance, not only provide scientific workers with justification for the faith which is in them, but also tend to "clear the air" of any lingering feeling of hostility between them and those whose labours are purely humanistic. The addresses of the sectional presidents cover a very wide field, almost the whole gamut of the sciences. Many of them deal mainly or exclusively with recent advances in specialised departments; others, like those on engineering and anthropology, are throughout historical; and again others, like the addresses to the educational and economic sections, discuss problems which are of perennial interest. In every case the standard attained is high, the contribution notable, and if we have any adverse criticism to make, it is that, from the point of view of the lay reader, too many of the addresses are concerned with specialised and recondite topics to the exclusion or subordination of matters which are of more obvious interest and importance; in other words, they may appear dull to the average man.

The meetings of the British Association are most useful in bringing together workers in many branches of science. In recent years the institution of joint discussions on border-line subjects has increased their utility; and of late there has been a noticeable levelling-up in the scientific value of the papers presented; all of which is to the good. The problem, therefore, consists in realising a harmonious balance between the requirements of the specialist and those of the lay public. It will, we believe, be generally admitted that addresses and papers should not, as a rule, resemble those which are given at ordinary meetings of specialised societies:

¹ The Advancement of Science, 1925. London: British Association, Burlington House, W.1. Price 6s.

the treatment should be broader and more in touch with human welfare—not necessarily material welfare.

From this point of view, some of the addresses and papers contributed to the recent meeting are open to criticism. About one-half of the addresses printed in the annual volume are obviously written by the specialist for the specialist. Although subjects relating to education (upon which nearly every other man claims to speak with authority) and to economics lend themselves more readily to popular treatment than others it has been repeatedly shown that even in very recondite branches of science it is possible to introduce matter which appeals to the man of average intelligence and education. As examples in point, we may refer to the addresses given this year to the physiological and psychological sections. The physiology of muscular exertion and the theory of intelligence do not at first sight appear inviting topics to the non-specialist, but the manner of treatment as well as the matter treated secured in these cases extended notices in the daily papers. Prof. Parks' address on the cultural aspects of geology was also framed in a manner likely to appeal to a wide audience. We do not, of course, wish to plead for a stereotyped form of presentation, and we are well aware of the great difficulties inherent in popular exposition, but we do urge that the interests of the Association would be better served if greater use were made of its unique opportunities for securing the infiltration of scientific learning into all classes of the community.

Possibly the specialisation of scientific work must prevent the proceedings of the sections from making more than a sectional appeal. If this be so, then the Association must be regarded chiefly as a professional organisation, like the British Medical Association and similar bodies, neither desiring nor expecting members of the general public to attend its meetings. Even then, we urge that more serious attempts should be made to improve both literary and oral exposition in presenting papers. We plead for a style of composition and exposition suitable at least for a general scientific audience, even if the lay public is left out of account. It is surely a reflection upon scientific training that so few who represent it are able to address a public or any other audience in a manner which will command attention or stimulate interest.

A few lecturers of this kind are available, and the Association does its best to secure them for the public lectures delivered to citizens, and to children, at each annual meeting. These lectures are not intended for members of the Association, and arrangements for them are in the hands of the Local Executive Committee. In these days of many kinds of entertainment and obtrusive advertisement, it is obvious that

wide publicity should be given to the citizens' lectures if good attendances are to be secured. This was not done at Southampton, with the result that the attendances at both these lectures and the children's lecture were far smaller than the lecturers or their subjects merited. Any good lecture agent would have secured large audiences for these lectures if they had been business undertakings, but as they were not, very few people in the town or neighbourhood were aware of them. This is not the way to further the purpose of the Association "to obtain more general attention for the objects of science."

The History of Telephony.

The History of the Telephone in the United Kingdom.

By F. G. C. Baldwin. Pp. xxvi+728+75 plates. (London: Chapman and Hall, Ltd., 1925.) 42s. net.

THIS large book on the history of the telephone in the United Kingdom gathers together in a single volume an immense amount of valuable historical research on the development in Great Britain of one of the epoch-making inventions of electrical science. The invention of the magneto-electric telephone and the reproduction by it of articulate speech at a distance is a striking example of the solution of a technical problem, long recognised as possible of solution, attacked by several inventors with very little success, yet finally accomplished by a stroke of genius in the very simplest manner.

The speaking telephone, far more than many other electrical inventions, may be credited to a single inventor, in that Alexander Graham Bell was the first to discover a method, imperfect though it was, of translating the changes of air pressure constituting speech wave sounds into corresponding changes of electric currents in a line wire, and the conversion of them back into sound waves at the receiving end. This use of what was then called an undulatory current in a circuit never completely opened made possible the electric transmission of speech as compared with the transmission of mere musical sounds. Like many other inventions, Bell's success came as a kind of accident in the manipulation of an appliance called a harmonic telegraph which was not originally intended or hoped to function as a speaking telephone. Mr. Baldwin sketches in brief outline in his first chapter the stages by which Bell was thus led to success.

The remarkable thing about the Bell magneto telephone, with its steel diaphragm, having such a limited number of modes of vibration, is that it should be able to transmit intelligible speech sounds at all. It is probable that a large part of its success depends not so much upon its own intrinsic powers as upon the wonderful ability of the human ear to guess from a mere

suggestion of a speech sound the intellectual meaning which that sound is intended to convey. The true air wave-form, with its complicated outline, is in fact very imperfectly reproduced by the telephone receiver diaphragm, but a mere hint enables the trained ear to interpret it.

Bell's invention, though effective as a receiver, was a very ineffective device as a transmitter, and if it had not been supplemented by the invention by Edison of the carbon transmitter, and by Hughes of the microphone, it is highly improbable that it would have fructified into practical utility or even passed beyond the stage of a scientific curiosity. The combination, however, of the variable resistance or microphonic carbon transmitter and the induction coil as a means of translating sound-wave motion into electric current variation, together with Bell's magneto-receiver for effecting the reverse transformation, gave a completely practical and simple solution of the telephone problem.

In his second chapter Mr. Baldwin describes the early operations and subsequent union of the Bell and Edison inventions and the early stages of invention in connexion with the evolution of a telephone exchange. But for this latter conception, which originated in America, the use by the public of the electric telephone would have been extremely limited. The pioneer work of the original Bell and Edison Telephone Companies in London, in establishing rudimentary telephone exchanges, is described by Mr. Baldwin in his second chapter, and also the story of the initial litigation between the Companies before the United Telephone Company was formed.

Chapter iii. opens with an account of the important litigation started by the Crown against the United Telephone Company to enforce against it the rights gained through the Telegraph Acts of 1863, 1868, 1869, under which the State purchased for about 10 million sterling the business of the pioneer electric telegraph companies. These original telegraph companies conducted their operations with diverse kinds of signalling instruments, and before long there arose a movement for "nationalising," as it is now called, the new methods of intercommunication. In order to prevent the Government monopoly being infringed by the possible invention of new types of electric telegraph, the Acts were drawn in such general terms that, when the telephone inventions made it possible to establish commercial exchanges worked for the convenience of "subscribers," the question was before long raised by Post Office officials, alarmed about their monopoly, whether the telephone was a telegraph within the meaning of the Acts.

The case was tried by Mr. Baron Pollock and Mr. Justice Stephen in November 1880 and decided against

the Company. Unfortunately, the case was never taken to the Court of Appeal or to the House of Lords for confirmation or reversal. The directors of the Telephone Company, doubtful of the issue and perhaps reluctant to dissipate their available funds on further litigation, accepted a proposal of the Post Office that they should bow to the decision of the Court of First Instance and take a licence from the G.P.O. for a term of years, and the payment of a royalty of ten per cent. of their gross receipts from all exchange business carried on within five miles of the General Post Office, London. Thus it came to pass that the fetters of State control were riveted on the limbs of the new industry; and in the following thirty years the General Post Office was able to extract from the telephone more than a million sterling in the form of royalties, for which the State had given no equivalent of actual value.

The important question, from the point of view of the general public, is whether it is to the advantage of the community that a business so technical, and involving the necessity for so much invention and scientific knowledge, should be under the control of the State at all. Arguments can be given for and against the contention. Government departments certainly do not provide a congenial soil in which enterprise, invention, or economical commercial progress can flourish. No young man entering a Government department finds that originality or initiative is encouraged or that it tends to fame and fortune for himself; in short, it does not pay, and hence he soon settles down to a steady but slow-going officialism. Moreover, Government departments are subject to the changes of policy incidental to successive administrations. Thus it has come to pass that succeeding governments in Great Britain have played with the telephone as a cat plays with a mouse. The dual control, partly by the G.P.O. and partly by a limited company, was for years disastrous to progress.

The history of the telephone in Great Britain is therefore in great part a revelation of Government ineptitude, and supplies solid reasons against that nationalisation of technical industries with which present-day socialists are so enamoured. It is sufficiently suggestive that none of the great inventions in connexion with telephony have originated with British Government officials. They did not invent the telephone itself, or originate the telephone exchange, or the dry core cable, loading coil, uniformly loaded cable, phantom circuit, automatic telephone exchange, or the thermionic telephone repeater. All these important inventions originated with private inventors and came to us mostly from the United States, where the telephone is not under Government control but is a private enterprise. Furthermore, the ideas of scientific men such as

the late Mr. Oliver Heaviside or Prof. Silvanus Thompson, who suggested improvements, were not followed up but even resisted by official electricians, and telephonic invention in Great Britain languished accordingly.

Returning, then, to Mr. Baldwin's book, we find that in the following twenty chapters he gives us an excellent account of the development of the great inventions which have been enumerated above. The gradual evolution of the telephone switchboard is illustrated by numerous valuable diagrams, and the replacement of the human element in it by the fully automatic exchange is outlined. The completely automatic telephone exchange by which, without any human intervention, a subscriber calls up another, finds out if he is already engaged, if not, converses with him, and finally switches himself out, is one of the most marvellous pieces of mechanism which the human mind has ever devised. Its elaboration has been due to many clever brains directed to a surpassingly difficult problem. The G.P.O. has now established in Great Britain a considerable number (about 25) of these automatic exchanges on various systems.

In the chapter on long-distance transmission, Mr. Baldwin only devotes a paragraph or two to another invention of cardinal importance, namely, the thermionic repeater, which has enabled a vast extension of telephonic range to be obtained. Suffice it to say that telephone electric currents are weakened by travelling along aerial lines or in cables. But a device called a thermionic repeater, which is a development of the thermionic valve invented by the present reviewer, is employed to reinvigorate these currents and send them on a farther stage with fresh energy. The importance of this invention is that it enables wires of smaller section, and therefore cheaper, to be employed. If the trunk telephone lines of Great Britain had to be relaid, it would be possible to save hundreds of thousands of pounds in mere cost of copper.

Taking the volume as a whole, we can say that Mr. Baldwin has given us a very readable and interesting history of the telephone in Great Britain. The book contains a large number of illustrations showing the development of various appliances, whilst much useful information in the form of tabular statistics is contained in the appendices. A good index completes a book which will certainly be highly appreciated by all telephone men and those who have to explore the history of any part of the subject. Lastly, a short introduction by Mr. Frank Gill, who was for eleven years engineer-in-chief of the National Telephone Company, and intimately acquainted with the history as well as technique of the subject, gives the reader an assurance of the trustworthy character of the history so well presented.

J. A. FLEMING.

The Contact Process for Oleum Manufacture.

The Manufacture of Sulphuric Acid (Contact Process).

By F. D. Miles. ("The Manufacture of Acids and Alkalis," by Prof. George Lunge. Completely revised and rewritten under the editorship of Dr. A. C. Cumming. Vol. 4.) Pp. xv+427. (London and Edinburgh: Gurney and Jackson, 1925.) 36s net

IN the realm of pure chemistry, few better examples than the chemical change between sulphur dioxide and oxygen can be selected to illustrate the general principles involved in gas reactions, whilst its value in the elucidation of the mysterious influences at work in the field of catalysis cannot be overestimated. The fundamental features of the contact process, as we now know it, were first described by Peregrine Phillips, a vinegar manufacturer of Bristol, in his patent of 1831, and to him belongs the credit of making the original scientific discovery and of realising its commercial possibilities. Nevertheless, no practical success had been attained when, in 1868 to 1872, the synthetic production of alizarin removed one of the chief reasons for this slow development—the absence of a market for fuming sulphuric acid.

At this time the sole maker of fuming acid was Baron Stark in Bohemia, the process used being substantially that of Basil Valentine (born 1394)—the decomposition of ferric sulphate obtained from "copperas-slate." No wonder that chemists turned their attention to the production of fuming acid in other places and by other methods. The publication in 1875 of a paper by Clemens Winkler, professor in the School of Mining at Freiberg, marked the beginning of most important developments. He recommended platinised asbestos as the catalyst in preference to platinised pumice or porcelain, and, in order to obtain the best results, postulated the necessity for having the sulphur dioxide and oxygen present in the stoichiometric ratio necessary for acid formation. The fact that for many years the latter statement was accepted and quoted by all classes of chemists shows how little attention the Law of Mass Action, enunciated by Guldberg and Waage in 1867, was receiving in 1875. Any chemist acquainted with this law could have shown the error in Winkler's conclusions by pointing to the equation of the reaction. Almost on the same day that Winkler sent in his manuscript, an application by W. S. Squire was lodged for a British patent, embodying the joint invention of Squire and Messel. The process was established at Silvertown and produced several tons of trioxide per week. The loss of activity of the catalyst, due to its accumulating such im-

purities as flue dust, was first noted by these workers, but its sensitiveness to specific poisons such as small traces of arsenic was not known until many years later.

In 1901 Knietzsch gave his famous lecture to the German Chemical Society, in which he described some of the work which had been carried out in the laboratories and on the plant of the Badische Company.

"This discourse," says Mr Miles, "in spite of defects and notwithstanding its many omissions, is still the most important ever recorded on the scientific and technical aspects of the oxidation of sulphur dioxide. Not only had Knietzsch and his collaborators examined the behaviour of platinum and other catalysts under various conditions of temperature and rate of flow of gas and supplied much-needed information about the physical properties of fuming acid and sulphur trioxide and their action on iron and steel; they had also found solutions of all the technical problems which had made difficult the use of pyrites burner-gases, abandoned the theory of Winkler, arrived at the unexpected conclusion that contact vessels require cooling and not heating, and had in general rendered the contact process so successful that it could henceforward not only produce fuming acid cheaply but actually compete with the chamber process for ordinary concentrated sulphuric acid."

Yet, prior to the War, the number of plants manufacturing oleum in Great Britain could be counted on the fingers of one hand. With the outbreak of war, a large supply of fuming acid became an urgent necessity, and the existing sources were quickly supplemented by many plants of great size and varying design.

Such are some of the main points in the fascinating history of the manufacture of oleum with which Mr. Miles begins his excellent book on the contact process. A survey of these facts fully supports the author's contention that the contact process is one of the foremost achievements of technical chemists, for undoubtedly the many difficulties that arose in the course of the pioneer work were solved more or less empirically by dint of hard work, the running of careful trials, and the gradual accumulation of data. However, Mr. Miles is optimistic and appreciative of the results which can and should accrue from the linking up of purely scientific and technical discovery, for, as he says, "the barriers dividing knowledge are broken down and we may hope to have in regard to the contact process in both technical and scientific aspects a body of information which from every point of view is equal to that applying to any other chemical change."

With the general treatment of the subject no one who peruses this volume can fail to be impressed. The author mentions as one of his aims the avoidance of a too sharp distinction between the technical and scientific aspects of the subject. In this respect he has been exceptionally successful, attaining an almost

perfect blending of the theoretical and practical considerations. How complex and intriguing are the numerous factors to be considered in the formation of the trioxide and its absorption may be gauged from the chapters on the properties of sulphur trioxide and oleum, gas equilibrium and velocity of reaction, catalysis and contact mass, gas purification and absorption of the trioxide. All these phases are dealt with in a lucid and authoritative manner, interposed with valuable suggestions for future research and development. The last three chapters in the volume describe Grillo-Schröder plants and the Tentelew and Mannheim processes, and contain important information of practical significance. Replete with excellent illustrations and nomographic charts, this volume is in every respect a noteworthy production, fully maintaining the great traditions which will always be associated with Dr. Lunge's treatises. - W. W.

British Scientific and Technical Books.

A Catalogue of British Scientific and Technical Books: Covering every Branch of Science and Technology, carefully Classified and Indexed. New edition, entirely revised and enlarged. Pp. xxii + 489 (London: British Science Guild; A. and F. Denny, Ltd., 1925) 12s. 6d net.

THE British Science Guild performed in 1921 an extremely useful public service in issuing a catalogue of British scientific and technical books. By donations from interested bodies and a number of publishers, and with the aid of what must have been a considerable amount of voluntary labour, the Guild has found it possible to issue a new edition without undue drain upon its own slender resources, and the result is eminently one upon which it may be congratulated.

In this edition the terms "scientific" and "technical" and the term "book" have been broadly interpreted, with the result that it contains more than 9500 titles, an increase of nearly 50 per cent. on the first edition. The entries are grouped into classes corresponding with the main and recognised divisions of scientific work, each division being arranged in sections on a subject basis, the entries in each section being in alphabetical order of authors. It is easier to criticise such a classification than to suggest an improvement, and it is hoped that the newly formed Association of Special Libraries and Information Bureaux will be able to render assistance in such matters as this. Undue dependence on the main classification is avoided by excellent author and subject indexes, but an illustration of the classification difficulty is provided, for example, by Prof. Burstall's "Energy Diagram for Gas," which is readily traceable through the author

index, but is not referred to in the subject index except under "Thermodynamics." In the body of the book the entry is made in the section on General Physics, Section ii.d, Gases, whereas its place is preferably under Mechanical Engineering, Section xviii., Internal Combustion Engines. It is also surprising to find Dr. Aston's "Isotopes" grouped in Chemistry, Section v.b, Physical Chemistry, and not referred to at all in the section on physics. It is placed consistently with the scheme of classification, but this tends to be a Procrustean bed to which the books have to be fitted. The grouping of the metallurgical section illustrates the main difficulty of making mutually exclusive sections when one section relates to materials (iron and steel, non-ferrous metals), while other sections relate to processes and methods (heat treatment, foundry practice, etc.). Close inspection of several of the main sections shows that nothing has been omitted.

It is, of course, impossible for the inexperienced student to dispense with the advice of a specialist in utilising an uncritical or unannotated collection, but this volume illustrates in an admirable way what British material is available, and it will be found constantly useful in both general libraries and the ever-increasing number of specialised technical libraries all over the country. In view also of the high reputation of British books abroad, it may well act as very valuable propaganda on behalf of British scientific literature.

Palæolithic Art.

Les Combarelles aux Eyzies (Dordogne). Par Dr. L. Capitan, l'Abbé H. Breuil, et D. Peyrony. (Institut de Paléontologie humaine: Peintures et gravures murales des cavernes paléolithiques.) Pp. iv + 192 + 58 planches. (Paris: Masson et Cie, 1924.) 200 francs.

THIS superbly illustrated volume, recording the palæolithic art of the cave of Combarelles, is the latest of the well-known series of works which started under the auspices of the late Prince of Monaco with "Altamira" in 1906 and continued with "Font de Gaume," "Les Cavernes de la région Cantabrique," and so on. These monographs have finally and for all time presented the palæolithic art of France and Spain to the student of prehistory, enabling him to do his work without having always to be visiting out-of-the-way localities and difficult caves.

More even than this has been accomplished, however, for in the texts will be found careful accounts of the systematic work done in the caves themselves, where the significance of every superposition of drawings was noted; also comparisons with outside matter are included. For example, in the volume under review, the chapters on the types of horse figured at Com-

bareilles and their relationships with the various breeds surviving to-day will not only be read with interest by prehistorians but will also be equally appreciated by the zoologist. The virgin ground broken long ago by Piette, Munro and Cossar Ewart has here yielded a rich harvest.

The cave of Combarelles is one of the most important palæolithic temples in the Dordogne. Although the art is nearly all engraved, there being scarcely any paintings, the beauty of the drawings and the skill employed has rarely been surpassed elsewhere. The animals figured include: horse (in large numbers), mammoth, reindeer, bison, ibex, bear, tiger, rhinoceros, fox, wild-ass, humans (sometimes masked), signs and so on. The age of most of this art is adjudged to be Lower Magdalenian—that is, a Magdalenian before the appearance of the barbed harpoon.

The present volume opens with an account of the discovery of the art and the situation of the cave, and this is followed by a description of finds from sites nearby, as well as an account of one or two objects from Combarelles itself. An inventory of the art on the walls and ceiling of the cave follows; the work concludes with important comparative chapters on the occurrence of the various species of animals and the figures of humans found, and a short discussion as to the age of the ensemble.

It is the plates, however, which naturally first attract the student. Even those of us who knew and had studied Breuil's tracings and photographs, both in the study and on the spot, will be delighted with the results appearing here. It was no mean feat for Breuil and his photographer to have worked for months on end in that most awkward of tunnels. Besides the clear, distinct figures there are numbers of intricate panels representing a series of complicated palimpsests. Although Dr. Capitan and M. Peyrony have done their part, to the Abbé Breuil remained by far the largest bulk of the work in the cave as well as the actual writing and preparing for press.

A monograph of high scientific importance like "Les Combarelles" ought to make our English publishers and printers pause and think. The price (200 fr.) is not excessive, and it is grievous to remember that no work of this standard could ever be produced in England at even triple the price. Once more is the Institut de Paléontologie humaine to be congratulated, and it is only to be hoped that further volumes will be soon appearing, giving prehistorians some more of that mass of unpublished material Breuil possesses. Perhaps next time there may appear an account of that equally important and still less known Spanish rock shelter art (Spanish group III.) belonging to the Late Neolithic and Copper ages.

M. C. BURKITT.

Our Bookshelf.

The Physical Chemistry of Igneous Rock Formation: a General Discussion held by the Faraday Society, the Geological Society, and the Mineralogical Society, October 1924. Pp. 411-501. (London: The Faraday Society, 1925.) 6s. 6d. net.

THE discussion on this subject arranged by the Faraday Society excited great interest, and the collected papers contain much that is of value. Whilst most of the speakers dealt with heterogeneous equilibria, and particularly with the crystallisation of minerals from magmas, one rather elaborate memoir on homogeneous equilibria was communicated by Prof. Niggli, of Zürich, in which certain considerations relating to the formation and decomposition of compounds in solution are applied to rock provinces of the Pacific, Mediterranean, and Atlantic types, a diagram being used to indicate the relationships, in such a way as to point to the differentiations which may be expected to occur during cooling.

Another question which recurs frequently in the discussion is that of the influence of volatile constituents on crystallisation. The possibility that pressure gradients as well as temperature gradients may be important is suggested by W. H. Goodchild and supported by G. W. Tyrrell, and the presence of volatile constituents is also invoked to explain the formation of alkaline rocks. Since experiments on magmas containing volatile substances can only be made in special apparatus capable of withstanding very high pressures, it has been urged that provision should be made in Great Britain for research in this field, and the paper by Dr. J. W. Evans outlines a very extensive programme of work which should be undertaken if means permitted, including the effect of shearing forces as well as of hydrostatic pressure.

Bowen's reaction principle comes in for some discussion, and the question is raised whether the methods used in metallography require much modification when they are applied to the study of such viscous and highly associated liquids as rock magmas. Prof. J. W. Gregory's detailed survey of the subject of magmatic ores leads to the remarkable conclusion that ores of magmatic origin are probably quite unimportant, all the famous deposits to which such an origin has been assigned having been shown to have been formed in other ways. The little volume is most interesting and suggestive.

A German-English Dictionary for Chemists. By Dr. Austin M. Patterson. First edition, with Addenda. Pp. xvi + 343. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 12s. 6d. net.

To compile a small dictionary from data easily available in larger works, is a comparatively simple task. To compile a small dictionary of a special character, like that now under review, requires not only judgment, accuracy, and application, but also a good knowledge of the languages and the science concerned. These qualifications Dr. Patterson possesses to an eminent degree, and therefore it occasions no surprise to learn that his "German-English Dictionary for Chemists" has been reprinted no less than five times, and that 21,000

copies of it have been sold since the first impression was made in 1917.

The book is excellent so far as it goes. It is obviously not intended for the linguistic expert, the professional translator, or for other serious students of German, but for the ordinary run of chemists, who to-day know little French and less German, it is remarkably good, being exactly what they require. With the aid of this small dictionary, such a chemist will be able to "make out" the meaning of almost any passage in a German chemical work; he will not, however, always be able to render it into precise and good English, because he will not always find the exact English equivalents of the German compound words he encounters. As a rule, such words are easy to understand, but alas! they are also easy to mistranslate, and they occur frequently in such branches as metallurgy, spectroscopy, atomic structure, economic and engineering chemistry. We hope, therefore, that when the work is revised, it will be found possible to include exact renderings of many more German compound words, so that we may be spared from errors like that made by the Frenchman who, when endeavouring to translate "hemisphere," looked up "hem" and "sphere," and then, uniting the French equivalents in unholy wedlock, wrote down the word—*demi-monde*!

Electrical Circuits and Machinery. By Prof. John H. Morecroft and Prof. Frederick W. Hehre. Vol. 2: Alternating Currents. Pp. xi+444 (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924) 20s. net.

THIS is the second of three volumes intended for the use of students in engineering colleges. The first was on continuous currents (now generally called in Great Britain direct currents). The final volume will describe "experiments." We think the authors have discussed their subject in a way which will be appreciated by the average student, who has generally a very limited time at his disposal. Although it is not sufficiently thorough to satisfy the consulting engineer, yet wherever possible without dragging in advanced mathematics, proofs are given. The art of the electrical engineer is ever advancing. Both the mercury arc and the thermionic valve rectifiers are included. Sub-stations with all their apparatus in the open air (outdoor sub-stations) are described. We notice that in the United States every large electrical company has an oscillograph, generally mounted on a truck, so that it can easily be transported to any point of the supply network.

We are glad that the authors insist that students must know the theory of the instruments they use. In too many cases students consider an ammeter, for example, as a piece of apparatus having two terminals, a pointer and a scale, and know little or nothing of what is happening inside. In alternating current machinery armature reaction plays the leading part, and due stress is laid on this. Particular attention is very properly devoted to the current and voltage relations of polyphase networks. Too many students are content simply to memorise the necessary formulæ without taking the trouble to understand their proofs. This slackness on their part will probably give them much trouble in the future, and they will never gain that confidence which is requisite for success.

NO. 2915, VOL. 116]

The Fauna of British India, including Ceylon and Burma. Edited by Sir Arthur E. Shipley; assisted by Dr. Hugh Scott. Coleoptera. Clavicornia. Erotylidae, Languriidae and Endomychidae. By G. J. Arrow. Pp. xvi+416 (London: Taylor and Francis, 1925) 30s.

THIS volume, which is the third contributed by Mr. G. J. Arrow to the "Fauna of British India" series, deals with three very closely related families of clavicorn Coleoptera, namely, the Erotylidae, Languriidae, and Endomychidae. They are all tropical groups that are but poorly represented in temperate regions. The Erotylidae recorded from the Indian fauna number 129 species, and Mr. Arrow has established the new sub-family Euxestinae for four exceptional genera which possess a rounded, solid club to the antenna. The Languriidae, with 110 Indian species, are not usually regarded as a separate family and most authorities place them among the Erotylidae. Mr. Arrow, however, considers them sufficiently distinct to merit family rank, but their affinities are so intermingled with the Erotylidae, Endomychidae, and Cryptophagidae that their taxonomic status is largely a matter of individual opinion. Unlike the Erotylidae and Endomychidae, the Languriidae feed as larvae in stems and the imagines are very characteristically elongated. The third family—the Endomychidae—includes 120 recorded Indian species included in three subfamilies.

It may be mentioned that in two features the present volume differs from its predecessors. First, there is a folding map of India and Ceylon, and secondly, there is an index of plant names. Both innovations add to the convenience of the users of the book. The illustrations include a chromolithographic plate and 75 excellent text-figures.

The whole work is well up to the standard of the previous volumes on Coleoptera, and Mr. Arrow is fortunate in being able to examine the original type-specimens in a large proportion of the species, a feature which gives additional value to his identifications.

A. D. I.

Christian Missions and Oriental Civilizations: a Study in Culture Contact. The Reactions of Non-Christian Peoples to Protestant Missions from the Standpoint of Individual and Group Behaviour. Outline, Materials, Problems, and Tentative Interpretations. By Dr. Maurice T. Price. Pp. xxvi+578 (Shanghai: Edward Evans and Sons, Ltd; London: G. E. Stechert and Co, 1924) 16s.

THIS book makes a wide appeal. It is of interest to those who are actively concerned with the work of Christian missions, to anthropologists, to psychologists, and sociologists, and to those who have to deal with the practical problems of administration. It approaches the work of the missionary from a novel point of view. It does not deal with spiritual, theological, or metaphysical interpretations as such; but it examines the reactions of non-Christian peoples to the Christian Church's attempt to convert them—both the initial and temporary responses and those which are more permanent. Missionary effort during the last one hundred years is surveyed from this point of view.

For the first time missionary effort has been studied as a natural phenomenon and as a social psychological

process, without partisanship or bias. The reader must not seek here for any panacea for the many ills arising out of the clash of cultures and ideals from which we are at present suffering in many parts of the world. This study is purely analytical. As the author points out, it is incomplete in the sense that further research is needed and consideration of the data available must be carried further in later volumes. The method is capable of an application wider than the mission field, and therefore deserves the careful consideration of all who are interested in the urgent problem of the future of primitive peoples.

Mechanical Design of Overhead Electrical Transmission Lines. By Edgar T. Painton. Pp. viii+274+26 plates. (London: Chapman and Hall, Ltd., 1925.) 21s net.

THE successful transmission of thousands of electrical horse-power by overhead wires over hundreds of miles is not only feasible, but has also been proved in almost every country to be attractive from the commercial point of view. Satisfactory operation has been attained by the continual attention that electrical engineers have been paying to the technique of design, and to the improvement of the quality of the materials used in construction. Continuous laboratory research and long experience have enabled them to anticipate operating difficulties, and combat them by selecting suitable materials and altering the design so as to raise the factor of safety. Of recent years long reports, papers, and patent specifications have been issued almost daily, and there are few who have the ability and the time to separate the grain from the chaff. This volume describes the latest constructional details, and makes references to the latest specifications issued by the British Engineering Standards Association, the American National Electric Light Association, and the Verband Deutscher Elektrotechniker. References are also given to many important papers published in the transactions of scientific institutions both at home and abroad. Novel data in connexion with steel cored aluminium conductors are given. These conductors are being extensively used, and necessitate changes in the details of transmission line design. This book can be recommended to both the practical and the academic engineer. The latter will see how many theorems given in examination papers have been modified to make them useful in practice.

Round the World in Folk Tales: a Regional Treatment.

Sixteen Stories from Various Lands, with a Chapter on their Meaning. Compiled and edited by Rachel M. Fleming. (Folk Stories for the Geography, History, and Reading Lesson.) Pp. xi+49+8 plates. (London: B. T. Batsford, Ltd., 1924.) 2s. net.

THE value of folk tales as illustrative material in education is now generally recognised. Miss Fleming has added to the indebtedness of teachers to her by the publication of this third collection of stories. It comprises sixteen stories drawn from widely scattered areas—Australia, Melanesia, Japan, China, America, Africa, Russia, and Brittany, to name some of the sources only. The bearing of the stories upon points of geography is perhaps more apparent than it was in the earlier volumes, and is further emphasised in an

introductory note. For example, "The Legend of the Flowers" from Australia is made to illustrate the effect of climate on vegetation and animal life, and in the same way, one of the Russian stories, extremes in climatic variation. Again character and quantity of food supply is a not unimportant feature which receives frequent mention, while the stories from Ireland and Brittany show the effect of the introduction of Christianity. The Bushman boy's account of some of the things told him by his mother might very well be used as the basis of a contrast in educational methods among civilised and uncivilised peoples. The bibliographical references are a useful guide for further study and add to the value of a book which should be widely used. The illustrations are interesting and well chosen, but might with advantage have been reproduced on a larger scale.

The Principles of Thermodynamics. By George Birtwistle. Pp. ix+163. (Cambridge: At the University Press, 1925.) 7s. 6d. net.

THIS admirable little book, based on lectures given by the author in the University of Cambridge to students of varied scientific interests, contains an account of the fundamental principles of thermodynamics and their main applications to the various branches of science. It opens with a brief account of the historical preliminaries leading to the two fundamental laws and the idea of entropy. After an account of the chief characteristic equations for fluids, the usual mathematical relations involving the thermodynamic potentials are discussed and applied to the more elementary cases of simple and compound systems. The book closes with four chapters dealing respectively with osmotic and vapour pressure, thermoelectric phenomena, specific heats, and radiation.

The whole treatment of the subject is brief and almost sketchy; but it is up-to-date, well-balanced, and wholly adequate, as no essential step is missed either in the physical argument or its mathematical development. The author has had the courage to cut out ruthlessly all matter which is irrelevant to his main theme, and the result is a thorough but handy account of the subject, in which the component parts are presented in their true aspect. No attempt is made at a critical survey of the fundamental ideas or at a discussion of the extensive statistical side of the subject; but these would obviously have been out of place in a first book on the subject. We may, perhaps, hope that the author has intentions of writing a second volume.

G. H. L.

Drogen und Drogenhandel im Altertum. Von Dr. Alfred Schmidt. Pp. viii+136+8 Tafeln. (Leipzig: J. A. Barth, 1924.) n p.

IT has been well said that no branch of knowledge can be adequately understood without an acquaintance with its history, and this applies in full measure to a knowledge of drugs. The study of the history of drugs, cosmetics, balsams, unguents, spices, etc., from the earliest written records to the present time, is so intensely interesting as to make it appear strange that so few pharmacognosists have devoted themselves to it. True, Tschirch, Schelenz, and a few others have collected data, but they have, as a rule, failed to present them in an attractive form.

From isolated details scattered among the works of numerous authors, Dr. Schmidt has endeavoured to build up a picture of the trade that was done in these materials, the extent to which they were used, and the routes by which they reached the various markets. He makes one realise that it was so considerable, and the traders so numerous, that thousands of years ago there were streets mainly occupied by their shops, and one can imagine one sees the buyers congregating there and comparing the wares offered.

To accomplish this has been a task of no inconsiderable magnitude, as any teacher can testify who has attempted to compile for his students a concise but intelligible history of drugs. To any one fairly conversant with German, the work is so fascinating that it can be read again and again. It contains a bibliography, and in addition there are numerous references in the text; it is full of most interesting details and is a valuable addition to the literature of pharmacognosy.

Qualitative Analyse und ihre wissenschaftliche Begründung. Von Prof. Dr. Wilhelm Böttger. Vierte bis siebente umgearbeitete und erweiterte Auflage. Pp. xvi + 644. (Leipzig: Wilhelm Engelmann, 1925.) 19 gold marks.

On reading this valuable work one is impressed by the fact that although the experimental data underlying qualitative analysis have changed but little, their interpretation has in many respects been revolutionised: the applications of the law of mass action and of the ionic theory of solution have brought order into the chaos and transformed what was once little more than a handicraft into a consistent and coherent science. Nearly twelve years have passed since the third edition of Böttger's work was noticed in these columns (December 18, 1913); the new edition is a very worthy successor to the old and gives a good idea of the advances that have been made in the interval. The first and more difficult part, dealing with the theoretical foundations, is particularly well done; the language is clear and simple, and the experimental illustrations are well chosen. Modern views on valency and molecular structure are treated at length, and there is an interesting section on electrolytes and Werner's theory.

In the experimental part are to be found many reactions of recent discovery, some of which are sufficiently specific to be used as tests without recourse to separation. The treatment generally is very full, and microchemical reactions have not been neglected. Books of this type are very few in these days of costly printing, and the appearance of the new and enlarged "Böttger" will be welcomed by all who are interested in this very old but still very fundamental branch of chemistry.

British Birds. Written and illustrated by Archibald Thorburn. In 4 vols. Vol. 1. New edition. Pp. xii + 176 + 48 plates. (London: Longmans, Green and Co., 1925.) 16s. net.

WE have received the first of the projected four volumes of a smaller and less costly edition of Mr. Thorburn's "British Birds," a book first issued on a sumptuous scale in 1915 and now out of print in its original form. The coloured plates, a new series, are again the principal feature, for Mr. Thorburn has a well-earned reputation

as an ornithological artist. They are usually clear and accurate, often beautiful, and on the whole well reproduced; a few, however, are noticeably less successful than the others. The text is undistinguished, consisting of very brief summaries of the usual text-book information plus a few comments, frequently in the form of quotations, upon habits or special points. This is unfortunate, for it is difficult to see what function a still rather expensive book giving so little information can fulfil.

One feels that the book should either have been brought within smaller compass altogether or have been expanded considerably in dealing with the more important birds. Either of these courses could have been followed had Mr. Thorburn been less subject to the fetish of that arbitrary category known as "the British list." Thus, no less than seven kinds of wheat-ear are each given a page, and all but two of them a place in the plates, whereas only one species is anything more than a very rare accidental wanderer to Britain. In a popular work there would be every advantage in dismissing accidental rarities with a bare mention. The confusion that there has been in ornithological nomenclature is to be regretted, but it does not help matters, now that some uniformity is being reached by general agreement, to find an author harking back for his standard to a work which was published in the previous century.

A Monograph of the Mycetozoa: a Descriptive Catalogue of the Species in the Herbarium of the British Museum. By Arthur Lister. Third edition, revised by Gulielma Lister. Pp. xxxii + 296 + 223 plates. (London: British Museum (Natural History), 1925.) 31s. 6d.

A THIRD edition of the monograph of the Mycetozoa by Arthur Lister has been prepared by Miss G. Lister and issued by the Trustees of the British Museum. Few groups of organisms have been so well catered for in the way of an accurate and well-illustrated systematic monograph: and the appearance of a third edition tells at once of the attractiveness of the organisms themselves and of the interest stimulated in any group when a sound treatise is available.

Biologists may have imagined that the Mycetozoa were fairly thoroughly known when the second edition, published in 1911 (which also introduced a revised nomenclature in accordance with the International Rules), included all additions to date. It is surprising, therefore, to note that no less than three additional genera, 46 species, and some 50 additional varieties, are incorporated in the present volume. The results of recent biological research are also included.

The work of revision having been in the experienced and accomplished hands of Miss Lister gives assurance that the new edition is of the same standard of excellence as its predecessor.

Faune de France. 8: Diptères; Tipulidæ. Par C. Pierre. (Fédération Française des Sociétés de Sciences Naturelles: Office Central de Faunistique.) Pp. 159. (Paris: Paul Lechevalier, 1924.) 25 francs.

THE present instalment of this useful series deals with the crane flies. Since the work is primarily intended for the identification of the adult insects, there is only a short account of their biology and metamorphoses.

Osten-Sacken's division of the family into Longipalpi and Brevipalpi is followed and four subfamilies are recognised, namely, Tipulinae, Cylindrotominae, Lomnobiinae and Trichocerinae. For the venation Tillyard's modification of the Comstock-Needham system is adopted.

The method of treatment of the family is by means of keys, which take the reader step by step from the subfamilies to the tribes and thence to genera and species. In the case of the larger genera the species are sorted out into groups in order to facilitate identification. The specific characters are further enumerated in a little more detail in the lists which follow the keys, and notes are given as to distribution and so on. The numerous text-figures are almost entirely devoted to the genitalia and venation, excepting two pages of illustrations which depict the larval and pupal characters of the Lomnobiinae. The work will prove useful to English dipterists, as very little has been published on the British forms for nearly forty years, excepting Edward's revisional notes (1921). A. D. I.

The Botany of Crop Plants: a Text and Reference Book.

By Prof. Wilfred W. Robbins. Second edition. Pp. xxi+674. (Philadelphia: P. Blakiston's Son and Co., 1924.) 3.50 dollars.

THE usefulness of this volume is indicated by the fact that a second edition has been called for in the comparatively short period of seven years. Opening with an outline morphological sketch, the author proceeds to give an account of the various crops grown in the United States, gathering together information that is otherwise very scattered. The crops are dealt with under the headings of their respective natural orders, the more important, chiefly cereals, being described in some detail. Bibliographies are appended to each crop or group of crops, but do not pretend to be complete. The classification of the varieties or types of crop is simplified by the free use of keys, many of which are original. A feature of the book is the "direct" method of labelling the very clear illustrations, thus rendering them more easy of reference for the student. A glossary of botanical terms and a good index round off a book that should prove of considerable value to agriculturists as well as to botanists.

Pecan-Growing By H. P. Stuckey and Prof. Edwin Jackson Kyle. (The Rural Science Series.) Pp. xiii+233+12 plates. (New York: The Macmillan Co., 1925.) 12s. 6d. net.

THE growing importance of the pecan-nut in American commerce has justified the production of this book dealing with the crop in all its aspects. The pecan, *Hicoria pecan*, is closely allied to the walnut, and now ranks second to the latter in the nut production of the United States. Propagation is not easy, and special attention is devoted to descriptions of the various methods of budding or grafting that it is necessary to employ. An interesting feature is the account of the National Pecan Growers' Exchange, an organisation for marketing the nuts by means of a grower's co-operative non-profit association without capital stock. Such a body tends to raise the standard of the crop owing to its system of careful grading and differential prices. Lax supervision in the earlier years of cultiva-

tion favoured the introduction and spread of many insect and fungus pests, which now need to be combated to prevent serious reduction of the nut crops. The volume concludes with a discussion of the food values and descriptive accounts of the many varieties of the pecan.

Distillation Principles. By C. Elliott. (Chemical Engineering Library: Second Series.) Pp. 166. (London: Ernest Benn, Ltd., 1925.) 6s. net.

MR. ELLIOTT'S book contains, on the whole, a clear and readable account of a subject which most students find difficult. In a few places the text is not so perspicuous as it might have been, but the general treatment is sound. Particular stress is laid on the work of Rosanoff, which the author says he has found helpful, and the methods adopted certainly appear practical and useful. A fair amount of mathematics is essential, but the full discussion of numerical results gives the treatment a sense of reality which is most gratifying. It may be noted (p. 24) that the molecular weight of hydrogen is not 2, and that 2 grams of hydrogen do not occupy 22.412 litres. Biot's vapour pressure formula (p. 21) is the only one given, whilst Kirchhoff's is perhaps more useful; Avogadro's law does not state (p. 34) that "the volumes of gases are proportional to their molecular weights." Useful tables are given in an appendix. The book can be recommended as a concise and accurate account of a difficult subject.

An Introduction to the Literature of Chemistry: for Senior Students and Research Chemists. By Dr. F. A. Mason. Pp. 41. (Oxford: Clarendon Press; London: Oxford University Press, 1925.) 2s. net.

THE idea of assisting the research student by explaining how to make use of the literature is a good one, and a satisfactory book on these lines would be most useful. Unfortunately, Dr. Mason has not made the most of his opportunity. He has omitted to mention many of the best works of reference, and his critical remarks are not always such as would meet with general agreement. The section on physical chemistry is particularly unsatisfactory, and no guidance as to consulting the literature is given in this part. In future editions, the author would do well to seek advice from specialists, and to find out what books are, in fact, most consulted in the large libraries. His lists read as though based on a rather arbitrarily selected private library.

Acid-Resisting Metals. By Sydney J. Tungay. (Chemical Engineering Library: Second Series.) Pp. 136. (London: Ernest Benn, Ltd., 1925.) 6s. net.

MR. TUNGAY deals with various types of acid-resisting metals, such as silicon-irons, lead and regulus metal, aluminium, stainless steels, monel metal, cast iron and steels, nickel and chromium alloys, copper and copper alloys, in an interesting way, and has succeeded in giving a large amount of useful information in small compass. The use of acid-resisting metals has changed many aspects of chemical engineering practice and holds out prospects of further applications. The information in the book, when it is not directly based on the author's own experience, is carefully compiled from good authorities, and the result is that one can rely on the correctness of the statements. The book can be warmly recommended.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Future of the British Patent Office.

THE burden of Mr Wyndham Hulme's letter (NATURE of September 5) is that, as regards basic principles in the granting of patents for inventions, there should be a reversion to the principles which obtained during Elizabethan and early Jacobean times, and that in every particular Patent law should be made subservient to the successful establishment of industries in Great Britain. Thus although a "manufacture" might have already been known, yet if it had not been reduced to practice, a valid patent should be obtainable by anyone who was the first to put the "manufacture" into practice. Further, Mr. Hulme contends that, if novelty is to be the test for validity of a patent, it is practically impossible for a thorough search to be made by a body of officials, and that since an administrative search for novelty has long been an economic absurdity, the growth of British industry should be stimulated by a relief of the patentee from an unduly high legal standard of novelty.

There is of course always much which deserves close attention in any of Mr. Hulme's observations upon Patent law and its administration and I regret therefore that I am not altogether in agreement with the views he is now expressing.

Dealing with the topics touched upon by Mr. Hulme, I think the nature of the consideration for a patent is quite clear, namely, the publication through the Patent Office of an invention which was new when the application for the Patent was made. I agree that the meaning of the term "new invention" has changed considerably during the last three hundred years. There is not much doubt that during early Jacobean times the test for novelty lay in the direction of discovering whether or no the patented invention had been "manufactured" in England. This arose from the fact that knowledge of an invention was much more likely to have been secured through it having been manufactured than through its having been described orally or in writing. But I doubt not that, even in these early times, "novelty" would have been destroyed if on a test case having been brought before the Courts, it had been proved that the industry or invention had been known in some way or other. Unfortunately, so few cases have been reported where patents were fought in early times. The decisions of the Privy Council are all right so far as they go, but the Council often acted despotically and was not very anxious to abide by the letter of the law where the supposed interests of the nation or the interests of favoured individuals were primarily concerned. A discussion, however, of the relation of the Privy Council to the Courts of Law is one that cannot be entered upon here beyond saying that there is ground for supposing that the Privy Council often usurped jurisdiction where patents for invention were in question.

When writing became a general method of transmitting information, it was not surprising that, early in the eighteenth century, the means for imparting information concerning a new invention was concentrated upon the "Specification" and that, in consequence, the prior publication, among other things, of a

writing which described an invention, should be held to be destructive of validity of a patent granted for that invention.

I think that there is a good deal to be said for the view that the original object of granting patents was the establishment of industries in England, and that if a patent was found not to have resulted in the establishment in this country as opposed to establishment in other countries, the consideration for the patent had failed. It is clear that the Courts of Law receded further and further from this view of the early law and that statute law attempted and still attempts to reinstate the original condition for the granting of patents. Whether the statutes have been successful or no is a matter upon which much diversity of opinion is present, and together with the question whether such restriction is advisable are subjects too big to deal with here.

As regards Mr. Hulme's two basic principles (a) and (b), I do not think that they are necessarily antagonistic, for in numberless instances the institution of a new industry has followed upon the disclosure of an invention. Indeed, I think it would be so difficult as to be impossible to grant patents upon the strength of the setting up of a new industry as opposed to the disclosure of an invention in writing deposited in a public office.

With respect to the granting of patents with relatively narrow claims, that necessarily and rightly follows when a search has shown that wider claims would interfere materially with the existing rights of the public. It is only just that when an inventor has added but little to the stock of public information, his monopoly rights should be proportionately reduced, and that when by an official search an inventor has been shown to be worthy of little protection, his patent rights should be virtually negligible. There is no reason, however, that when an individual has truly discovered an invention of immense and wide importance his patent, as is the case at the present day, should not be proportionately broad and his security of the highest. This means that I do not agree that when security is at its highest, restraining power is necessarily at its lowest.

The anonymous letter which Mr. Hulme quotes scarcely seems relevant. The practice of the United States Patent Office as regards claims and the law of the United States in respect of the interpretation of specifications and claims differ so much from ours that, granting what is said to be correct, the letter is but a complaint about patents granted in the United States of America.

With respect to search for novelty to which Mr. Hulme also refers, the complaint really comes down to saying that since perfection cannot be obtained in practice, it were better to have no search at all. I cannot agree to this, and I should have thought that the more thorough the search the more secure is the patent.

As regards relief of the patentee from the unduly high legal standard of novelty as mentioned by Mr. Hulme, it must be remembered that members of the public have the right to employ any extant information which has not been the subject of a patent, the term "extant information" including the associated knowledge which is the property of the expert or operative. It can scarcely be right that a patent should be granted to one who for his own purposes selects extant information, and that the public should be restrained from utilising what, before the patent was granted, they had a right to employ.

Concerning overlapping claims, I understand that it is the practice of the Patent Office to prevent this so far as it is possible. All of us are desirous of simpli-

fying procedure, but in our zeal for simplification we must be careful not to admit abuses.

I agree entirely with Mr. Hulme's conclusion; it is only when we face at close quarters the means to be adopted that we may find ourselves at variance.

WILLIAM MARTIN.

1 Elm Court, Temple, E.C.4.

The Theory of Hearing.

A SERIES of communications by Scripture, Wilkin-son, and Hartridge concerning the mechanism of hearing has recently appeared in NATURE. In Prof. Scripture's most recent letter (February 14, p. 228), the work of Fletcher (*Phys. Rev.*, March 1924) and that of Wegel and Lane (*Phys. Rev.*, February 1924) are stated to be irreconcilable with the so-called "resonance theory" of hearing and as being in accord with a "pattern" or "deformation" theory which he advocates.

The definition of resonance in the popular sense involves the psychological factor of perceptibility of continued free vibrations after the driving force has ceased to act. If "resonance" is understood in this popular sense, the "resonance theory" of the cochlea is improperly named. Helmholtz took great pains to show that in order to explain "shakes," the vibrating areas on the basilar membrane cannot be "resonant." The damping of these selective areas obtained from data given in the Wegel and Lane paper indicates for the mid range of audible frequencies that the amplitude of free vibrations of each area diminishes to a value $1/e$ (roughly $1/3$) of its initial value in from 1 to 10 vibrations or in from 0.01 to 0.001 seconds. The vibrations are apparently not aperiodic but are highly damped. We may, therefore, conclude that the theory in question amply accounts for the suppression of free vibrations, *per se*, beyond the point of perceptibility, and, consequently, does not lead to the prediction of what Prof. Scripture calls "jangle" or "noise and jumble of sounds."

A description of the pattern of vibration of the basilar membrane as predicted by the "resonance theory" will perhaps make the matter clear. Fig. 1

FIG. 1.

shows, in longitudinal section, the pattern of deformation of the basilar membrane in response to a sustained musical tone of pitch 256 (middle C). The amplitudes are, of course, enormously magnified when compared with the length of the membrane. This figure is made from quantitative data obtained from the paper (Wegel and Lane) referred to above. The pattern consists of a series of vibrating areas on the basilar membrane roughly elliptical in contour. These areas are larger and farther apart at the apical end of the membrane and closer together and tending to overlap near the basal end. The area, *a*, vibrates at 256 cycles or vibrations per second and corresponds to the fundamental or cord tone described in Prof.

Scripture's book "Elements of Experimental Phonetics." Area *b* vibrates at 512 cycles and corresponds to the second harmonic or first over-tone. Each harmonic is represented by a characteristic area. At points where two successive areas overlap, the membrane vibrates at the two frequencies simultaneously, causing a more or less irregular stimulation of the nerve terminals. If the relative amount of higher harmonics, which produces the overlapping areas, is so great that the resultant sensation is largely due to them, the sensation is that of poor musical quality.

If the pitch of the tone is changed, the pattern moves bodily along the membrane without great change in form. When, however, the pitch is exceedingly low, the areas, *a*, *b*, *c*, tend to be closer together and wider. When very high the maxima of the overlapping areas are crowded closer together. The loudness of the note depends on the absolute amplitudes of vibration of these areas and the quality depends chiefly on the ratios between the amplitudes. The sounds from a bell or cymbals, or from a vibrating plate or bar, produce patterns on the basilar membrane consisting of vibrating areas differently spaced from those shown in the figure. A noise disturbs the whole membrane instead of exciting separate areas in the simple manner indicated in the figure. Owing to the high damping, the vibrations of the membrane remain sensible only while the sound continues.

When a musical chord is sounded the pattern is more complex than in Fig. 1. The pattern for a tone of pitch 512 is like that in the figure for 256, except that it is displaced to the left a distance *a* *b*. If both tones are sounded together the resultant pattern consists of a superposition of the two patterns. The areas set in vibration by the higher tone coincide exactly with the even numbered areas excited by the lower one. The resulting amplitude at any one of the even numbered areas may be either smaller or greater than the amplitude there produced by either tone alone, depending on the phase differences of the tones. If the octave is not exact, beats result at the even numbered areas. If these beats are very rapid a discord results. A chord, consisting of several notes, results in a pattern on the basilar membrane consisting of the superposition of a number of patterns, properly spaced, each like that in the figure, one for each note in the chord.

The portamento or glissando, in order to be well executed, must take an appreciable time, say $\frac{1}{4}$ or $\frac{1}{2}$ second. A portamento through the octave 256 to 512 is represented by a shift of the pattern in the figure through a distance equal to *a* *b*, the pattern at any time being identical in position and form, so far as it would be possible to distinguish, with a pattern produced by a sustained tone of the identical pitch falling on the ear at that instant. The pattern resulting from the sound of Prof. Scripture's accelerated toothed wheel behaves similarly. A voiced sound in speech is represented by an appearance of such a pattern on the basilar membrane, a movement to and fro to correspond to the variation in pitch of the chord tone, a correlated variation in actual and relative amplitudes of vibration of the areas to correspond to changes in loudness and quality respectively, and a disappearance, all in sensibly exact synchronism with the spoken sound.

The sense of pitch of a tone is determined from the position of the root area, *a* (Fig. 1), of the series of areas on the membrane. When, for some reason, the lower harmonics are very faint or absent from the tone, the root and first few areas are missing from the pattern, but the root position, and therefore the pitch of the tone, may be inferred by a psycho-

logical process of association. The habit of association of the root area with the pattern position, therefore, accounts for Fletcher's experiments independently of the existence of non-linearity in the ear. When more and more low harmonics are eliminated, e.g. with filters, as in Fletcher's experiments, the sense of a definite pitch fades and merges into a high pitched noise having poor musical value.

At the higher levels of loudness, however, non-linearity (presumably greatest at the malleo-incal joint) undoubtedly comes into play. This compensates to a certain extent for cutting out the missing lower frequencies by resupplying them in more or less reduced amounts as difference tones, to the complex vibrations entering the cochlea. The result of this process is to give a more definite sense of pitch than association alone could do. Just what relative parts are played in Fletcher's experiments by association and by non-linearity is not certain, but experience certainly indicates that for loud sounds the latter plays a considerable part.

It will now be seen that Prof. Scripture's remarks concerning his own hypothesis apply equally well to the "resonance theory." Quoting from his article above referred to: "According to this [Scripture's] theory, the basilar membrane alters the linear movement of the stapes into a change of form in three dimensions. Every external vibration produces a pattern deformation of the membrane. This pattern is communicated to the brain. A single vibration of a clarinet tone produces a definite pattern in three directions on the basilar membrane. The mental quality of the clarinet tone represents this pattern. When this vibration is repeated regularly, the clarinet quality appears to be based on a tone of definite pitch."

An extended Helmholtz or resonance theory is the only present dynamical theory which conforms to the well-known laws of vibrational mechanics. The cochlear model of Wilkinson (*Journal of Laryngology and Otology*, September 1922) has demonstrated concretely that this type of mechanism is selective after the manner supposed by the resonance theory.

Progress in this field of investigation would be more rapid if those who are at work in it made greater efforts to understand each other's methods and terminology.

Bell Telephone Laboratories, Inc.

The Distribution of the Two Electrical Zones in the Atmosphere.

I HAVE examined the fair weather potential gradient on several mountains in the Bernese Oberland, and find that the positive zone, in summer at midday, extends from sea-level to above the Jungfrau (13,671 ft.). When observations at greater heights are available it may be found that it reaches up to between that and 20,000 ft. above sea-level in Central Europe.

As the positive potential was lowest before sunrise, and reached a maximum in the afternoon which was maintained until near sunset, it is possible that the outer negative zone approaches near to the earth's surface during the night, and recedes during the hours of daylight.

That the properties of this zone on the mountains are due to positive gas ions, is proved by the study of mountain mists. In the simplest cases the formation of mountain mists can indeed be followed by the eye, but at times those drifting from and covering the Bernese Oberland extend for several miles, and their origin and nature are then uncertain.

In most cases I find, on electrical examination, that the "clouds" surrounding the mountain tops in summer are in reality ground mists. They proved

to be positively charged on the Eiger, Jungfrau, Fischerhorn, Wetterhorn, and Faulhorn, and in each case they possessed the property of increasing the fine weather positive potential at the position temporarily, due to causes I have already described (*NATURE*, May 30, 1925, p. 836).

Electrical examination seems to be the only certain method of distinguishing between mountain mists and clouds, for on one occasion during broken weather a true upper cloud, negatively charged and optically indistinguishable from mist, descended for a time and surrounded the summit of the Faulhorn. Significantly, the temperature, which had stood at 10° C. for some hours, fell to 4° C. very rapidly. Hail, rain, and snow on the Faulhorn (8800 ft.) were always negative after the passage of the positive sheath.

When the magnificent panorama, seen in cloudless conditions from the summit of the Faulhorn, was examined about sunset I noted that there are two optical zones in the atmosphere, which are not noticeable at lower altitudes or when the sun is higher in the sky. The upper was clear and brilliant, and there was a lower, grey, hazy zone which rose from the ground-level to several thousand feet above Pilatus (7000 ft.) and Nollen (8800 ft.). The zones were most easily traced against the darker northern background, being lost among the dazzling snow-capped peaks of the Oberland.

During a cloudless sunrise the same zones were apparent, but the junction was considerably nearer to the summit of Pilatus than at sunset. It was when the lower edge of the sun's disc entered the lower zone that its red coloration became visible, and the Alpine glow commenced. As the lower zone extended higher above the horizon in the evening than at sunrise, this seems to account for the superiority of the sunset coloration, for at sunrise the solar disc quickly emerges above the lower zone.

It seems to me probable that the two optical and electrical zones are identical, and that the red colorations of sunset and sunrise are therefore largely due to absorption of solar radiation by positive gas ions (together with associated water molecules?). If further investigation confirms this view, an optical method of determining the height of the positive layer above the ground is provided, for the time of entry of the sun's disc into the lower zone can be fairly sharply determined on still cloudless evenings. The height of the lower layer is variable in strong winds and unsettled weather. Strong ionisation and absorption of solar radiation may occur in the outer layer of the positive zone.

In the light of a two-layer atmosphere the accepted explanation of the mirage may require revision.

As the height of the positive zone appears to be mainly a function of local absorption of solar radiation, recombination during darkness, resulting in shrinkage, we may expect the outer negative zone to approach much closer to the earth's surface in the Arctic and Antarctic circles during polar winters, and such thinning out of the positive zone may be a factor in the phenomena of the Aurora. A significant fact in this connexion is the absence of thunder and lightning near the Poles, to which Dr. Simpson has directed attention (*NATURE*, April 14, 1923, Supplement, p. x). I recently explained (*ibid.*) that disruptive discharge is due to the intense electrification resulting from the formation of the positive sheath about the negative clouds when the latter descend quickly into the lower positive zone, especially about the vanguard. Where the clouds do not descend into the positive layer there would be no sheath and no lightning.

Observations of the height of the positive zone during daylight and darkness are urgently wanted.

Ticlio (15,885 ft.), at the head of the Peruvian Central Railway, should provide an accessible site for the tropics. Alpine meteorologists have their choice of several positions. The mountains of northern Scandinavia, and Spitsbergen, would provide valuable data nearer the Pole. Once charted, mathematicians can calculate from the relative motion of the upper air and the earth how much of the earth's magnetism is explicable, and wireless experts can appraise the influence of the zones in long-range transmission.

In conclusion—a word of warning. I have previously shown that the enormous quantities of positive gas ions poured out from steam locomotives makes observation in England uncertain, and near towns entirely misleading. In Swiss valleys this factor is now negligible; but another disturbance exists there. At Grindelwald the spray from the turbulent Lutschine, and numerous waterfalls and cascades, carries its negative charge to considerable distances—200 yards on either side of the stream near the gorge. Water (like all conductors) in the open air has an induced negative charge on it in fair weather, and on severance the spray carries the negative charge with it.

The Motion of Eruptive Solar Prominences.

IN the issue of NATURE for July 4, p. 30, Mr. Evershed has reviewed a paper by Edison Pettit on the "Forms and Motions of the Solar Prominences." Dealing with the motion of eruptive prominences, Evershed thus summarises the opinion of Pettit: "The memoir concludes with a theoretical discussion of the nature of the repulsive force acting on prominences. Radiation pressure is rejected as inadequate, and the periodic ejection of showers of electrons from a disturbed area in the photosphere is suggested tentatively."

I have recently contributed a paper to the *Astro-physical Journal* in which the motion of eruptive prominences is discussed at some length. Working on the lines initiated by Saha and Milne, I have shown that selective radiation pressure provides the motive force for the motion of prominences. The selective radiation pressure is due to the bright patches or filaments which develop on the solar photosphere and are always found associated with eruptive prominences. St. John has recently shown that the spectra of the faculae and filaments show the lines of Ti⁺ much enhanced over those obtained from the undisturbed photosphere, and hence the conclusion is that they are regions of higher temperature.

Milne has shown that the high level Ca⁺ atoms emitting H and K lines are supported against gravity by the pressure of the photospheric radiation. When regions of the photosphere get locally heated the equilibrium in the region above is disturbed, and Ca⁺ emitting H and K and hydrogen atoms emitting the Balmer lines acquire an accelerated velocity. The motive power is thus obtained from the excess of radiation pressure due to the development of filaments at the base over the solar gravity.

Pettit, however, has shown that the motion is not accelerated but uniform for some time and then actuated by impulses. A steady velocity can only be reached if the particles move in a resisting medium. Probably the frictional force is supplied by the Einstein coefficient of resistance

$$R = \frac{8\pi h^2 \nu^4}{3c^5} \cdot \frac{e h \nu / kT}{e h \nu / kT - 1} \cdot \frac{B_{1 \rightarrow 2}}{1 + e^{-h \nu / kT}}$$

where $B_{1 \rightarrow 2}$ is Einstein's probability factor of

NO. 2915, VOL. 116]

absorption. Thus Pettit's results are not inconsistent with the theory. But in some cases, as Evershed has remarked, the motions of the eruptive prominences decidedly show continuous acceleration. These cases may be explained thus: The Einstein coefficient of resistance R works out to be a small number. The radiation pressure, on the other hand, may increase to a sufficiently high value, if the fluctuation of temperature or the size of the bright patch at the base is large enough. In this case the prominence will reach a great height before anything of the nature of a constant terminal velocity is acquired. In the meantime the velocity will continually increase, but the absolute magnitude of the acceleration will continually decrease. The impulsive increments in velocities are due to the sudden changes of temperature at the base.

All electrical theories must be discarded, for large motions are observed in the case of lines of hydrogen which are due to neutral atoms. Electrical forces cannot act on neutral atoms.

For detailed argument reference is to be made to the original paper.

RAMANI KANTO SUR.

Physics Department,
Allahabad University,
July 29.

I AGREE in a general way with the view that the motion of the eruptive prominences, and of the absorbing gases in novae, may be best explained by selective radiation pressure.

The structure of the chromosphere itself suggests an outward movement along innumerable streams or jets, which are perhaps based on the brighter spots in the rice-grain structure of the photosphere.

There is a difficulty when we study the distribution of the larger eruptive prominences with respect to the faculae, or brighter regions of the sun's disc. While it may be difficult to locate precisely the origin of eruptions when observed at the limb, they often seem to occur in high latitudes outside the spot-zones, and they appear usually to be connected with the larger patches of absorbing gas which are photographed on the disc of the sun in the calcium lines or in H α . These patches tend to lie outside the faculous regions, either in high latitudes or in longitudes intermediate between the great regions of sunspot disturbance. There is thus no evidence that the photosphere underlying these prominences is brighter than normal.

On the other hand, eruptions of a somewhat different character are observed in the immediate neighbourhood of sunspots, and these may be connected with the faculae. In rare instances they are accompanied by a phenomenon suggestive of the outburst of a nova, namely, a great but temporary increase of brilliancy in the photosphere, such as was observed by Carrington and Hodgson in 1859. Such disturbances are usually associated with line-shifts indicating motions of the order of hundreds of kilometres per second.

J. EVERSHERD.

Spermatogenesis of Spiders and the Chromosome Hypothesis of Heredity.

FROM certain observations which I have recently made, it would appear that the spermatogenesis of some spiders exhibits interesting peculiarities which do not readily accord with the rigid scheme required by the chromosome hypothesis of heredity.

I have more especially studied the spider *Palystes natalius* Karsch; but certain other spiders have

similar peculiarities in their spermatogenesis. The spermatogonial nuclei divide by amitosis only, and no trace of mitosis was seen in the numerous sections examined (Fig. 1). The spermatocyte nuclei form a more or less typical spireme in which many "chromomeres" develop (Fig. 2). The spireme breaks down and the "chromomeres" are left free; they grow into rounded chromatin granules of considerable size (Fig. 3). From these spermatocytes, spermatozoa arise in two ways, as follows:

(1) The spermatocyte nucleus buds or fragments in a somewhat irregular manner and gives rise to a small cluster of nuclei, each of which becomes surrounded by differentiated cytoplasm (Figs. 4-7). These small cells are the spermatids, and with the most careful observation it is not possible to affirm that only four spermatids are formed from one spermatocyte; in fact the number seems to be irregular and usually more than four. The nucleus of the spermatid becomes hollow and the chromatin concentrates at one pole and gives rise to the spermatozoon, which afterwards becomes spread over the swollen cytoplasmic vesicle like a fish-embryo stretched over its yolk-sac.

(2) The numerous chromatin granules of the spermatocyte condense and form a considerable

very considerable amount of amitosis normally occurs, and with the present evidence it seems totally impossible to assume that the offspring of cells which have divided by amitosis are incapable of dividing by typical karyokinesis.

It would be obviously absurd to suppose that the mechanism of heredity differs fundamentally in certain spiders from that in other organisms, and if these observations are duly confirmed, and I can see no escape from them, the upholders of the chromosome hypothesis, which naturally hangs on its weakest link, will have to be content with a much less rigid chromosome behaviour than is usually assumed.

A detailed account of the observations is being prepared for publication. ERNEST WARREN.

Natal Museum.

The Transmutation of Uranium into Uranium X.

As described in the *Journal for Applied Chemistry* (Berlin, Leipzig, No. 32, 1924), the present writer succeeded in 1922 in observing the transmutation of mercury into other elements, when submitted to the effect of a strong electric discharge. This discovery

was described in a manuscript deposited under G 56485 IV/12h on May 3, 1922, in the German Government Patent Office, where it may be seen by anybody. It is therefore incorrect to state that Miethe first observed the transmutation of mercury.

This must be expressly stated here in order to assert the priority of the

number of large masses resembling definitive chromosomes, but when first formed there seems to be no constancy in size, and also there is no definitely fixed number. Afterwards these chromatin masses become more or less rounded and uniform in size and the cytoplasm of the spermatocyte disappears almost entirely (Figs. 8-12). There is thus formed a compact cluster of oval, or rounded, free chromatin-bodies. Each of these bodies becomes hollow and produces one spermatozoon which is differentiated peripherally.

When mature the spermatozoa originating in this way are somewhat smaller than those formed according to the first method described above. These uncoiled or unexpanded spermatozoa may occur in abundance, mixed with expanded forms, in the semen contained in the spermathecae of the female spider. From this account it is clear that the "spermatocyte" produces far more than four spermatozoa.

It is of special interest to note that in the second method of spermatogenesis, traces of achromatic spindles may occur sporadically in association with the clusters of chromosome-like bodies, and these bodies may even become temporarily arranged in an erratic manner in the equatorial plane. It is as though the ancestral condition is not completely forgotten.

These peculiarities in the spermatogenesis of Palystes are doubtless associated with the fact that in the development of the tissues of the embryo a

present writer and to justify the further experiments carried out during the period 1922-1925 in a domain which was offering no promise at all at that time. After the discovery of the transmutation of mercury, it was natural that other elements, especially uranium and thorium, which are subject to spontaneous disintegration, should likewise be examined for the possibility of artificial transmutation.

For this purpose the behaviour of uranium and thorium and their salts in the electric arc and in the glow discharge in evacuated tubes has been examined. In no case could there be observed an alteration in the radioactivity or in the chemical activity. A perceptible transmutation effect was, however, unexpectedly found when strong rushes of momentary high-tension currents were sent through a narrow fused quartz tube provided with tungsten electrodes and containing mercury and uranium oxide. The tube was fixed vertically in a stand, so that the mercury filled the lower part of the tube and one tungsten electrode was completely covered by it. On the surface of the mercury was a relatively thin coating of uranium oxide which had been carefully freed from radioactive by-products, especially from uranium X, before it was introduced into the quartz tube. The sparking distance between the tungsten electrode and the mercury-uranium oxide electrode was about 15 cm. The intensity of the electric discharge varied between 0.3 and 0.4 amp.

Under the influence of repeated electric discharges during about thirty hours, relatively strong and

increasing radioactivity, measured according to the β - and γ -rays method, showed itself. The tube, hermetically sealed, was also laid on a photographic plate enclosed in an aluminium box. After six hours a very perceptible blackening appeared on the part of the photographic plate corresponding to the quartz tube. The contents of the tube were dissolved in nitric acid. From the solution the artificially produced radioactive material was separated by all the known methods by which uranium X can be separated from uranium. Observation of the decrease of the radioactivity showed the half-period time to be that of uranium X. The identity of the radioactive material generated with uranium X was thereby proved. The β and γ ray activity of the uranium oxide freed from the mercury varied between 1.4 and 20 times the radioactivity of an equally large amount of uranium oxide in equilibrium with its decay products, and increased proportionally to the energy applied and to the time.

One obtains even a greater production of uranium X if one makes, in analogy to the experiments of Nagaoka, as described in NATURE of July 18, the electric discharges pass within a thick-sided quartz or porcelain vessel between a tungsten point and mercury covered with a thin coating of vaseline and uranium oxide. This coating possesses such a high electric resistance that, even when applying the highest tensions which can be obtained, one is obliged to diminish greatly the sparking distance in order to obtain a discharge. This proceeding offers the advantage that the energy is concentrated into a very small space. Consequently one can show, after half an hour's work, the production of relatively large quantities of uranium X. It should be stated, of course, that before the tests all parts of the apparatus were examined as to radioactivity and found not to be radioactive.

The production of uranium X considerably in excess of that produced by spontaneous decay is to be explained only by the fact that, under the influence of the electric force, an acceleration of the radioactive transmutation of uranium takes place.

A. GASCHLER.

Motzstrasse, 72,
Berlin, W.30.

Some Simple Characteristic Relationships among the Ferromagnetics.

THERE are some simple relations existing among the ferromagnetic bodies which no doubt have a fundamental significance. If we calculate the ratio of the critical temperature on the absolute scale (θ) to the maximum intensity of magnetisation (I_0) for each of the ferromagnetics, we obtain the following values for θ/I_0 .

Iron	$1058/1817 = 0.58 = 2 \times \frac{2}{7}$
Cobalt	$1348/1422 = 0.95 = 3 \times \frac{2}{7}$
Nickel	$661/552 = 1.19 = 4 \times \frac{2}{7}$
Magnetite	$808/431 = 1.83 = 6 \times \frac{2}{7}$

Thus θ/I_0 is proportional to the simple numbers 2, 3, 4, and 6. The fraction $\frac{2}{7}$ is the numerical constant in the equation to the critical temperature, namely,

$$\frac{\theta}{I_0} = \frac{8a'}{27R},$$

where a' is the constant of the intrinsic field and R' is the reciprocal of Curie's constant.

We may ask if a new ferromagnetic material were to be discovered would it fit into this scheme; in

short, are these simple whole numbers necessary to ferromagnetism?

In Heusler's alloy we have such a new ferromagnetic material, and an examination of its properties provides one answer to this question. Recently Prof. Thompson kindly supplied me with a sample of this alloy, prepared in the metallurgical laboratory of the University of Manchester, and experiments with it show that its critical temperature is 355°C . or 628° on the absolute scale, and the maximum intensity of magnetisation is approximately 420. Hence the ratio of θ/I_0 is $628/420 = 1.50$, and this is very nearly $5 \times 8/27$. Thus Heusler's alloy conforms to the whole number rule, and, moreover, it fills the vacant space between nickel and magnetite, so that the consecutive numbers from 2 to 6 are now complete. These numbers are exactly whole numbers within the accuracy with which θ and I_0 are known.

When it is remembered that three of these ferromagnetics are metallic elements, one is a definite chemical compound and another is an alloy of three non-magnetic metals, these results are all the more remarkable.

There are one or two other simple relations closely connected with the foregoing: for example, the ratio of the maximum intensity of iron to that of nickel is 3.3, and the ratio of the intensity of cobalt to that of magnetite is likewise 3.3. Similarly the ratio of the critical temperatures of iron and nickel is 1.60, and of cobalt and magnetite 1.67; so that these ferromagnetics fall into two closely related groups.

Planetary Densities and Gravitational Pressure.

WITH reference to Mr. Mallock's letter in NATURE of July 4, I beg to point out that the gravitational forces in his supposed envelopes will increase their density to a value comparable with that of a solid unless the planets are very hot indeed. The stability of the belts and spots on Jupiter and Saturn is a serious objection to the existence of such thick envelopes.

As to the compressibility of solids, the electrostatic theory of molecular structure is inconsistent with great increases of solid density. Surely Mr. Mallock's chalk experiment indicates that in the lower chalk the conditions are nearly crystalline and not that simple compression can produce important changes in density.

HERBERT CHATLEY.

The Word "Australopithecus" and Others.

IN answer to Dr. Lucas's letter (NATURE, Aug. 29, p. 315) it may be said that although scientific names need not be literature, and therefore need not follow any philological rules, yet where they pretend to be derived from Greek, or Latin, or any other particular language, good taste demands that they should conform to the structural system of that language.

We "scientists" are contemptuous when the unscientific misuse our terms: if we wish to avoid the contempt of literary folk, we should be careful how we use theirs.

Organic Evolution.¹

By C. TATE REGAN, F.R.S.

FOR any profitable discussion of the origin of species it is essential to know what we mean when we use the word "species." In Nature we find that a number of similar individuals, with similar habits, live in a certain area; such an aggregation of individuals may be termed a community. It is unfortunate that this word has sometimes been used for dissimilar and unrelated organisms that occur together—for example, the animals found on a muddy bottom in the North Sea, or the plants of a range of chalk hills—but I am satisfied that the word "association" is more appropriate to these, and that "community" is the right name for a number of similar individuals that live together and breed together. All this is preliminary to my definition of a species. A species is a community, or a number of related communities, the distinctive morphological characters of which are, in the opinion of a competent systematist, sufficiently definite to entitle it, or them, to a specific name. Groups of higher or lower rank than species can be defined in a similar way. Thus a sub-species is a community, or a number of related communities, the distinctive morphological characters of which are not, in the systematist's opinion, sufficiently definite to merit a specific name, but are sufficient to demand a sub-specific name. Similarly a genus is a species, or a number of related species, the distinctive morphological characters of which entitle it, or them, to generic rank.

There are, of course, many species so distinct from all others and so uniform throughout their range that every one is agreed about them; but frequently the limits and contents of a species, as of a genus, are a matter of opinion. No systematist has, or should have, any rule as to the amount of difference required for the recognition of a species or a sub-species; he is guided by convenience. In practice it often happens that geographical forms, representing each other in different areas, are given only sub-specific rank, even when they are well defined, and that closely related forms, not easily distinguished, are given specific rank when they inhabit the same area but keep apart.

I have seen a species defined as a stable complex of genes—or words to that effect—and Bateson, without exactly defining a species, has insisted that those systematists who distinguish between good and bad species are right, and that the distinction between the two is not simply a question of degree or a matter of opinion. There is some truth in this; in the absence of exact knowledge, seasonal or sexual differences have been regarded as specific, and hybrids, as well as varieties that differ from the normal in some well-marked character, have been given specific names: these are certainly bad species. There is truth also in Bateson's contention that species are qualitatively different from varieties, if we restrict this word to the kind of varieties he has specially studied and do not use it for communities that differ from each other in morphological characters.

According to Bateson the principal qualities of species are morphological discontinuity and interspecific

sterility; but to the implication that these have been suddenly acquired, I would reply that in Nature there is every gradation from communities that are morphologically indistinguishable to others that are so different that every one is agreed that they are well-marked species; and it is not surprising that when morphological differentiation has proceeded to this extent it should generally, but not always, be accompanied by mutual infertility. That morphological discontinuity in a continuous environment which appears to Bateson to support the theory of the discontinuous origin of specific characters is seen to be the final term of a habitudinal discontinuity that began with the formation of communities that were at first morphologically identical. Bateson's argument, that the Natural Selection theory, or any theory of gradual transformation, demands that the ancestral form from which two species have diverged should persist as an intermediate is seen to be quite fallacious if we get a firm grip of the idea of the division of a species into communities, followed by the evolution of each community as a separate entity.

A great deal of work has been done, especially on our more important food-fishes, in making biometrical analyses and investigating the life-histories of the different communities.

I have studied with particular attention the fishes known as char, or salmonoid fishes of the genus *Salvelinus*. Char are very like trout in appearance, but have orange or scarlet spots instead of black ones; they inhabit the Arctic Ocean and in the autumn run up the rivers to breed in fresh water, often forming permanent freshwater colonies in lakes. There are many such colonies in the lakes of Scandinavia, of Switzerland, and of Scotland, Ireland, and the Lake District of England; the formation of these colonies must date back to glacial times, when these Arctic fishes occurred on our coasts and entered our rivers to breed. These lacustrine communities show considerable diversity in habits and also in structure; for example, the char of Lough Melvin in Ireland are quite unlike those of Loch Killin in Inverness in form, in coloration, in the shape of the mouth, and in the size of the scales; these differences are sufficient to entitle them to be regarded as different species, and I have so regarded them; but now I doubt whether it is not better to look upon all these lacustrine char, however well characterised, as belonging to the same species as the migratory char of the Arctic Ocean, for once you begin giving specific names to lacustrine forms of char you never know where to stop. But if we were to exterminate the char in the British Isles and on the Continent, except in a dozen selected lakes, we should have left a dozen well-marked forms which it would be convenient to recognise as species. A somewhat similar problem arises in the classification of man; it is convenient to place all the living races in one species. But if there were only Englishmen and Hottentots we should probably regard them as specifically distinct.

In our British char, habitudinal segregation—the formation of communities in lakes—has been followed by a geographical isolation which commenced at the

¹ From the presidential address delivered at Southampton on August 28 before Section D (Zoology) of the British Association.

end of the glacial period, when the migratory char retreated northwards. The char of each lake have evolved separately, and one can see clearly how many of the differences between them are related to the conditions of life; for example, the large eyes of the Loch Rannoch char, which lives in a very deep lake, and the blunt snout and rounded subterminal mouth of several kinds which always feed at the bottom. I confess that I do not understand why the scales are much smaller and more numerous in the char of some lakes than in those of others, but I suspect that these differences in scaling are the expression of physiological differences, and are the result of differences in the environment or in the activities of the fish.

The genus *Salmo* comprises about ten species from the North Atlantic and the North Pacific, and I have shown that the salmon and trout of the Atlantic form one natural group and those of the Pacific another. Our own salmon and trout are two closely related species; both of them range in the sea from Iceland and northern Norway to the Bay of Biscay, both enter rivers to breed, and in both the young fish, known as parr, remain in fresh water until they are about two years old and six inches long, and then go to the sea. From Mr. F. G. Richmond, a well-known pisciculturist, I have the information that although at certain seasons the parr of both salmon and trout may eat the same kind of food—for example, both take flies at the surface—yet on the whole their food and feeding habits appear to be different. Salmon parr seek their food, such as insect larvæ, small molluscs and crustaceans, on the bottom, whereas young trout tend to keep in mid-water and to subsist more on water-borne food; thus the salmon parr may be hunting for food in a stretch of shallow rapid water, while the young trout wait for it in the quieter water just below. When they are about six inches long the parr of both species become silvery and are termed smolts; the trout smolts go to the sea in a leisurely manner, hanging about the estuaries, and the older fish frequent the coastal waters; but the salmon smolts make straight for the open sea and there grow much faster than the trout, attaining a weight of several pounds in a year.

I have gone into these details because I think it is important to establish that two closely related species in the same area have different habits, and to a large extent avoid competing with each other.

The morphological differences between salmon and trout are slight. The salmon, more active and a stronger swimmer, is more regularly fusiform in shape and has a more slender tail and a more spreading and more deeply emarginate caudal fin, differences of the same kind but not of the same extent as between a perch and a mackerel. The rows of scales between the adipose fin and the lateral line are usually fewer (10 to 13) in the salmon than in the trout (12 to 16); but this may be directly related to the fact that the tail is more slender. On an average the salmon has one ray more in the dorsal fin than the trout, and I am tempted to regard this as a step towards that increased number and concentration of the dorsal rays which is so characteristic of swift-swimming pelagic fishes. The last difference between the two species—the smaller mouth of the salmon—may be related to the food and feeding habits of the parr. In structure as in habits the salmon

is more specialised than the trout, and may have evolved from it. The salmon is found on the Atlantic coast of North America, where there are no trout; but I think this is because its habit of going farther out to sea has given it a greater opportunity of extending its range. There can be little doubt that the differentiation of these species has been not geographical but habitual, comparable to the differentiation of the coastal and open-sea herrings.

In every river and lake that it enters, the trout forms freshwater colonies, and on the other side of the Atlantic the salmon does so fairly readily, although not nearly so generally as the trout does on this side. In Europe, trout being present, the salmon forms freshwater colonies only in exceptional circumstances. Thus Lake Wenern in Sweden, now cut off from the sea by inaccessible falls, has a stock of salmon; there can be no doubt that in former times salmon entered the lake and bred in its tributaries, and that some of the smolts, when they reached the lake on their seaward migration, considered this very large lake a sufficiently good substitute for the sea to stay there, and so founded a lacustrine race.

Freshwater colonies of trout are found in the Atlas Mountains and in the countries north of the Mediterranean eastwards to the Adriatic, proving that in glacial times the range of sea-trout extended southward to the Mediterranean. The rivers of Dalmatia and Albania are inhabited not only by trout but also by fish of another species, known as *Salmo obtusirostris*. This little fish, which never grows larger than fifteen inches long, has all the structural characters that distinguish salmon from trout, and, indeed, looks very like an overgrown salmon parr; but when compared with salmon of the same size it is seen to differ in having a considerably smaller mouth, weaker teeth, and more numerous gill-rakers (15 to 18 instead of 11 to 14 on the lower part of the first arch). In fishes generally the number and length of the gill-rakers—projections from the gill-arches that prevent food from entering the gill-chamber with the respiratory current—are related to the nature of the food; thus, in exclusively piscivorous fishes, such as the pike, they are represented by a few short knobs, and in feeders on minute plankton organisms they are very numerous, long, slender, and close-set. It has been recorded that *Salmo obtusirostris* subsists mainly on the larvæ of Ephemeridæ, which are very abundant in the rivers it inhabits, and there can be no doubt that the small size of the mouth, the feeble dentition, and the increased number of gill-rakers are related to this diet.

The presence of this fish in the rivers of the east side of the Adriatic seems to me to point to the probability that in glacial times salmon, as well as trout, occurred in the Mediterranean, and that in these rivers some of the salmon parr, tempted by the abundance of parr food, preferred to continue the parr life instead of going to the sea as smolts, thus forming a freshwater colony in quite a different way from the salmon of Lake Wenern. The question may be asked: If these fishes are derived from salmon and live in the same way as salmon parr, how can their differences from salmon be adaptive? The reply to this is that the size of the mouth in the salmon parr must have some relation to the fact that it is going to become a salmon, feeding on fishes in the sea,

and that, as *S. obtusirostris* grows to twice the length of a salmon parr, we should expect the number of gill-rakers to be increased, for it is not number but the size of the interspaces that is important in relation to food.

The work of Dr. Johannes Schmidt on the viviparous blenny (*Zoarces viviparus*) is of great interest. He found that samples of *Zoarces* from various parts of the Kattegat and Baltic differed slightly, but generally had an average of about 118 vertebræ, but that in the shallow Danish fiords the number was less, and decreased progressively the farther the distance from the sea. Conditions of temperature, salinity, etc., are very different in the different fiords, and I am inclined to think that the critical character common to all of them is that they give the *Zoarces* an opportunity of leading a quiet life amidst a plentiful supply of food; hence the fiord *Zoarces* can be distinguished at a glance from those outside by their shorter and deeper form. For example, in the Mariager Fiord, a narrow inlet about twenty miles long, the average number of vertebræ decreases from 115 at the mouth to 111 about seven miles inland and 110 about fifteen miles inland; two samples from the extreme end of the fiord and from a point four miles from the end both showed exactly the same average, 109.3.

There can be no doubt that the fiords were originally populated from the outside, and it seems likely that the decreased number of vertebræ in the fiords is related to the lesser activity of the fiord fish. Evolution has proceeded to such an extent that the *Zoarces* of the Roskilde Fiord differs from that of the Kattegat more than does the European eel from the American, and these are generally regarded as good species. But the repetition of the same phenomenon in different fiords, and the continuous gradation from one form to another, make it impossible to recognise species here. *Zoarces* are very stationary, but possibly the young are more migratory than the adults. If we suppose that these fishes move on an average a mile a year, or even less, and mate with the nearest fish of the opposite sex, we can understand how the tendency to form a pure fiord race is hampered by continuous interchange, and how the influence of the outside form gradually diminishes until in the innermost waters it is not felt at all and isolation is accomplished. In each fiord a series of intermediates, hybrids if we like so to term them, connect two well-differentiated communities, one in the sea, the other in the inner waters of the fiord.

These detailed examples are sufficient to illustrate my view that some form of isolation, either physical or produced by localisation or by habitudinal segregation, is a condition of the evolution of a new species. The effects of physical isolation, due to the formation of a barrier, are well seen in comparing the fishes of the Atlantic and Pacific coasts of Central America, most of which can be paired, one species being found on the Atlantic side and its nearest ally on the Pacific side. The effects of habitudinal segregation are, as it seems to me, seen in the cichlid fishes of Lake Tanganyika, where there are ninety species that appear to have evolved in the lake from two ancestral forms; the differences between these species in the form and size of the mouth, and in the dentition, are an indication that their diversity is related to specialisation for different kinds of food.

The whole of my work leads to the conclusion that the first step in the origin of a new species is not a change of structure, but the formation of a community either with new habits or in a new or a restricted environment. For some species we know fairly certainly what has happened, and where, when, and why: Shall we ever know how? Experimental attempts to repeat the operations of Nature might perhaps give us a clue, but I do not expect one from experiments of the kind that are so fashionable nowadays.

For example, if *Salmo salar* and *Salmo obtusirostris* could be bred together, it would not matter much whether the hybrids were sterile or fertile; and if they were fertile it would not interest me to know that the variation in their offspring could be squared with the factorial hypothesis by the ingenious assumption that there were several factors for both larger mouth and smaller mouth and for fewer gill-rakers and more gill-rakers. Even if the number of gill-rakers in either species could be increased or decreased by thyroid extract, I should still be unconvinced that we had got much nearer to the root of the matter. . . .

Throughout, the evolution of fishes illustrates the same principles. Changes of structure have been intimately related to, and may even be said to have been determined by, changes of habits, and especially changes of food and of feeding habits. Evolution has been adaptive, but modifications of structure that were originally adaptive persist when they are so no longer; they become historical and the basis for further adaptive modifications. I am satisfied that these principles, which I have illustrated by examples from the group I have specially studied, have a general application.

Darwin's theory of evolution was that it had been accomplished mainly by natural selection, aided by the inherited effects of use and disuse. Whether that theory be permanent or not, it was put forward by a man pre-eminent for his wide knowledge and his great reasoning powers, who knew the facts that had to be explained and gave us a theory that explained them. The "Origin of Species" still remains the one book essential for the student of evolution.

Darwin has been criticised because, we are told, he did not know that there were two sorts of variations—mutations, which are inherited, and fluctuations, which vary about a mean and are not inherited. But when you point out to a mutationist that the heredity of many fluctuating variations has been proved—parents above the mean, for example, giving offspring above the mean—he tells you that that shows that the variation is not really fluctuating, but only apparently so, and that a large number of "factors" must be involved. This is in effect a complete withdrawal, for it amounts to an admission that Darwin was right if he considered that these types of variation differed only in size and frequency.

There are other critics, however, who admit that at any rate some fluctuations are inherited but say that the effect produced on a population by selection is limited; elimination of certain types will change the average, but will produce nothing new. This criticism has also, as it seems to me, been disproved experimentally; for example, by De Vries, who from two plants of clover in which a few leaves were four-lobed produced by selection a variety in which the number of

lobes of the leaves varied from three to seven, fluctuating about a mean of five. Incidentally this experiment shows the relation between mutations and fluctuations.

The criticism that many specific characters are non-adaptive merely amounts to this, that we do not know the meaning of many specific characters. Moreover, we are not likely to for a long time, for a prolonged study would be necessary to understand fully the meaning of the differences between any two species, to determine which characters were adaptive, which historical, which due to the environment, and which the expression of metabolic differences.

If these criticisms of the natural selection theory can be met, it does not follow that it is a complete theory. It may be a sufficient explanation of certain types of evolution, and one cannot wonder that those who have studied mimicry in insects are firmly convinced of its truth; but the evolution of the dodo, and of the blind fishes of subterranean waters, put rather a strain on the theory and almost demand the recognition of the inheritance of the effects of use and disuse.

If this be admitted, if the adaptive responses of an organism to changed habits and changed conditions make it possible for subsequent generations to respond with greater effect, then the part played by natural selection in evolution of this kind would be subsidiary, the selection of those individuals who responded earlier or better than their fellows. How well this idea fits in with that fundamental generalisation, the law of recapitulation, which states that ontogeny tends to repeat phylogeny, and that the more remote the ancestor the earlier it will be represented in the developmental history! This generalisation, based on embryological data, has since received strong support from palaeontological evidence.

Most people are aware that a flat-fish when first hatched is symmetrical and swims vertically, but that at an early age one eye migrates round the top of the head to the other side, and the little fish sinks to the bottom and henceforth lives with the eyed side uppermost. But perhaps it is not so well known that it has been shown that almost as soon as the fish is hatched the cartilaginous supraorbital bar above the eye that is going to migrate begins to be absorbed, and is eventually represented only by short processes of the otic and ethmoid cartilages, with a wide gap between them. Through this gap the eye migrates, with the result that, when ossification begins, the main part of one frontal bone is on the wrong side of its eye. The flat-fishes are an offshoot of the perch group, and it is known that some of these have a habit of resting on one side. If such a fish found it profitable to lie in wait for its prey in this position, it would naturally try to make some use of the eye of the under side, pressing it upwards against the edge of the frontal bone. In the flat-fishes the migration of the eye into and across the territory of the frontal bone, prepared for by the absorption of the cartilaginous precursor of the frontal bone before the eye shows any sign of migration, may well be interpreted as the final stage of a process thus initiated.

You will have seen, then, that I am inclined to accept Darwin's theory as a whole, including both natural selection and the inherited effects of use and disuse, at any rate until some better explanation of the facts is forthcoming. But still there are difficulties,

and to illustrate them I must give one more example from the fishes.

The most primitive spiny-rayed fishes are the Berycoids, which flourished in Cretaceous times; in some of these the vertebræ number 24—10 præcaudal and 14 caudal. In many families of Percoids, not at all closely related to each other, we find this number of vertebræ is a constant family character; for example, all the genera and species of sea-breams (Sparidae), red mullets (Mullidae), chætodonts (Chætodontidae), grey mullets (Mugilidae), and barracudas (Sphyrænidæ) have 24 (10+14) vertebræ. The conclusion is inevitable that this is a primitive percoid character derived from a berycoid ancestor. Yet we have clear evidence that whenever the circumstances demanded it this number could be decreased or increased. There is no variation and therefore no material for selection; also the number of vertebræ is settled at a very early stage, and no fish can increase or diminish that number in its lifetime. Psettodes, the most primitive living flat-fish, has 24 (10+14) vertebræ; it is simply an asymmetrical perch. It has a large mouth and strong, sharp teeth, and its principal movements are probably short dashes after fishes that come near enough to be caught. But in other flat-fishes the number of vertebræ is greater: in the sole, which feeds on small invertebrates that it finds in the sands, and swims along with undulating movements of the whole body, the number is about fifty, and in the tongue-soles (Cynoglossus) there may be so many as seventy vertebræ.

We are almost compelled to believe that muscular movements, the efforts of a fish to swim in a certain way, may lead to an alteration in the number of muscle segments of its descendants; the number of vertebræ is, of course, determined by the number of muscle segments. This is an extension of the Lamarckian theory, and some may regard it as a teleological speculation unworthy of serious consideration; some may even think that, as my suggested explanation is incredible, we have here another example of the truth of the mutation theory, which in effect states that it is only by accident that a structure has a function.

Many biologists have adopted Weismann's germ-plasm hypothesis so whole-heartedly that they seem to regard it as a final disproof of Lamarck's theory. But when we consider that in progressive evolution, as in the development of the individual, increasing complexity of structure and localisation of functions is accompanied by co-ordination of the activities of all the parts, that differentiation and integration go together and the organism remains a unit, the so-called "inheritance of acquired characters" seems no more unlikely in the most advanced Metazoa than in the simplest unicellular organisms; and in some of these it has been proved.

When I read Huxley's essays as an undergraduate I was greatly impressed with his remark that "Suffer fools gladly" was very good advice. If a man does not agree with you, try to find out why he thinks as he does; you may discover the weakness of your own position. We should not adopt theories as creeds and denounce other theories as heresies. We are more likely to make progress towards the solution of the problem of evolution if we keep open minds and take broad views.

The British Association: Connexion with Oxford.

AT the close of the first meeting of the British Association, held at York in 1831, the assembly stood adjourned to Oxford, the Rev. Prof. William Buckland becoming president-elect. Before the meeting dissolved, a speaker declared that in his opinion the Association was destined "greatly to enlarge the boundaries of science, and in so doing advance the many interests of human nature which depend upon the improvement of knowledge." It was all very tentative then, a matter indeed of faith, and faith sustained hope.

The train was thus laid for the second meeting held at Oxford in 1832. Since that date three other gatherings have met in the city, namely, 1847 (Sir R. H. Inglis, Bart., F.R.S., president); 1860 (Lord Wrottesley, F.R.S., president); 1894 (the Marquis of Salisbury, K.G., F.R.S., president). Next year, as we know, H.R.H. the Prince of Wales will occupy the presidential chair at Oxford.

Buckland, at the time of his appointment as president, was an enormous asset to the well-being of the first-born of York—a child able to walk, scarcely to run. He was a fellow of the Royal Society, and a past-president of the Geological Society. Moreover, he possessed agreeable social qualities, not least of which was a keen sense of humour. He had a habit of carrying about with him a large blue bag, containing fossils. Once, he said, he paid a visit to Sir Humphry Davy. "Has Dr. Buckland not called to-day?" inquired Sir Humphry. "No, sir," said the servant, "there has been nobody here to-day, but a man with a bag, who has been here three or four times, and I always told him you were out."

Buckland's address upon taking up the duties of his office was brief, in no way comparable with present-day extended surveys. He, however, gave a lecture on the fossil remains of the Megatherium. Cuvier had died on May 13 in the same year, and Buckland took occasion to give eloquent expression to the loss sustained by the death of that illustrious naturalist and leader. In the mid-week, at a general meeting, the first award of the Wollaston gold medal was made by Roderick Murchison, the president of the Geological Society, to William Smith, the acknowledged "Father of English Geology."

A voluminous report was presented by J. F. W. Johnstone on the recent progress and present state of chemical science. At an evening meeting Dr. Ritchie delivered a lecture on "Magnetic Electricity," with reference especially to recent discoveries of Faraday. Brunel gave an account of the attempt to carry a tunnel under the Thames.

At a Convocation, honorary degrees were conferred on Sir David Brewster, Robert Brown, John Dalton, and Michael Faraday, a "hodge-podge of philosophers," commented Keble.

Fifteen years had elapsed before the Association met again at Oxford in 1847. By then the permanence and stability of the organisation was fully assured, the boundaries of scientific effort advanced in all directions. The chair was taken by Sir Robert H. Inglis, member of Parliament for the University. We may conclude that the latter qualification really led

to his selection. He was a politician, one who opposed the repeal of the Corn Laws; a country gentleman with a genial manner, and capable of making friends; one also who took great interest in learned and religious societies, but, as chronicled by his biographer, "with many prejudices and of no great ability." We get a glimpse of views entertained by the president of the wonder-working electric telegraph. Sir Robert Inglis expressed regret that so great a discovery had been inadequately welcomed in Great Britain. Yet in the discharge of public business was it not important? He had had an opportunity of examining the telegraph in the lobby of the House of Commons, by means of which communication passed to distant rooms. He gave specimens of information thus conveyed: "Committee has permission to sit until five o'clock"; and among questions sent down were the following: "What is before the House?" "Who is speaking?" "How long before the House divides?"

John Couch Adams, the discoverer of the planet Neptune, made personal acquaintance with Leverrier at this meeting, and both were Sir John Herschel's guests. Leverrier's indications had supplied the basis for the location of the planet in 1846, but months earlier Adams had set down the data.

Dr. Schunck discoursed on colouring matters. Edwin Lankester read a paper "On the Plant which yields Gutta Serena," and prophesied its application as probably "very extensive." Owen, too, was at the meeting, and Ruskin, as secretary of the Geological Section. The youthful Huxley sent from H.M. *Rattlesnake* a paper on the corpuscles of the blood of *Amphioxus lanceolatus*. Faraday exhibited three specimens of diamonds received from M. Dumas, which had been subjected to intense heat. Joule read a paper (the third) on the mechanical equivalent of heat, which was, remarks Mr. Howarth, heard by both Faraday and Thomson (afterwards Lord Kelvin), the second of whom perceived that "it contained a great truth and a great discovery."

The Association did not return to Oxford until 1860, Lord Wrottesley becoming president. For four years (1854-58) his lordship had occupied the presidential chair at the Royal Society, earlier (1841-43) that at the Royal Astronomical Society. Hence he brought distinction and experience to his new office. Lord Wrottesley's address dealt rather fully with astronomical subjects. The important event of the opening of the New Museum at Oxford was referred to as an omen of bright hope in the diffusion of science. It is well to go back upon the past and quote the president's remarks respecting practical applications of chemistry. "We may refer," he said, "to the beautiful dyes now extracted from aniline, an organic basis formerly obtained as a chemical curiosity from the product of the distillation of coal-tar, but now manufactured by the hundred-weight in consequence of the extensive demand for the beautiful colours known as mauve, magenta, and solferino." In physiology, note was made of great and steady advances in the chemical history of nutrition, and of the electricity of nerves and muscles. The recent return of McClintock from the search for Sir John Franklin

was alluded to. The "Voyage of the *Fox* in the Arctic Seas" had been published late in 1859.

Passing to sectional details, it is incumbent to recall two papers read at Oxford at this time, respectively by Dr. Daubeny and Prof. Draper, of New York. Darwin's "Origin of Species" had appeared in 1859, of which by 1860 no fewer than eleven editions had been issued. These communications offered but cautious approbation of Darwin's researches. In itself, Draper's paper embodied an attempt to show that the advance of man in civilisation does not occur accidentally or in a fortuitous manner, but is determined by immutable law. From his work on physiology, published in 1856, he gave his views in support of the doctrine of the transmutation of species, the transitional forms of the animal and also the human type, the production of new ethnical elements or nations, and the laws of their origin, duration, and death. We must go outside the official Report of the Association for the year to piece together the records of the controversy and storm of words which waxed and raged round these communications; in a sense they were but stalking-horses, in any event traps for the unwary. Yet, looking back upon this mixed chapter of scientific and clerical polemics, the happenings all seemed inevitable. The stage was set, the disputants in place. Prof. Buckman sent a further report, on experimental plots in the botanical garden of the Royal Agricultural College, Cirencester, while Lawes and Gilbert again entered the domain of classic inquiries with a paper on the "Composition of the Ash of Wheat grown under various circumstances." Capt. Maury, of the U.S. Navy, had written to the president urging attention to Antarctic exploration, concluding cheerily with the words, "So trusting and hoping that you will join with me in the cry 'Ho for the South Pole!'" William Fairbairn reported experiments to determine the effect of vibratory action and long-continued changes of load upon wrought-iron girders.

In 1894 the Association again chose Oxford, after what Lord Salisbury, the president, and Chancellor of the University, termed "a long and dreary interval of separation of thirty-four years." Consequently a new generation participated in the proceedings of the reunion. The gathering was a great success, 2321 persons taking up membership, while no fewer than 77 foreign members attended, including Prof. Mittag-Leffler, Prof. Ludwig Boltzmann, Dr. S. P. Langley, M. Cornu, Prof. E. Van Beneden and Prof. Strasburger. One is painfully conscious in looking over the roll that time has brought about the removal of many eminent personalities in science since Oxford last received the Association.

Certainly the most notable occurrence at the meeting was the announcement by Lord Rayleigh and Prof. William Ramsay of the discovery of a new gas in the

atmosphere—argon. It fell to Sir Henry Roscoe to propose a vote of congratulation.

The president's address was prefaced by the open confession that he was, after all, only a layman, and "all the skill of all the chemists the Association contains will not transmute a layman into any more precious kind of metal." Nevertheless, the discourse provided a distinctive summary of advances, and comments thereon. In Lord Kelvin's view there was throughout "the spirit of the student, the spirit of the man of science." Prof. Huxley seconded a vote of thanks. It was reserved for an eminent mathematician and publicist to write later: "We find nothing in it which shows either the student or man of science; it teems with fallacious conclusions; and whatever may have been intended by the author, it can only serve as an appeal to the gallery, which is occupied by the reconstructed theological party."

In one of the sections Hiram Maxim gave a description of his experiments on flying by means of aeroplanes. Mr. Henry Balfour, in a paper on the evolution of the bow as a musical instrument, gave the aboriginal races of Africa and India the credit of providing the prototype of many of our best stringed instruments. Mr. Preece discoursed on signalling through space. Sir Andrew Noble told of his methods for measuring pressures in the bores of guns; that the earliest attempt, by direct experiment, to ascertain pressures developed by fired gunpowder, was that made by Count Rumford; but Sir Andrew pointed out assumptions and erroneous determinations. Lord Salisbury attended Prof. Rücker's address in the mathematical section; afterwards an adjournment was made to the Clarendon Laboratory to hear Lord Kelvin describe experiments on the electrification of the air. Prof. H. B. Dixon, president of the section of chemical science, took as his subject "An Oxford School of Chemistry." "If it be a true saying," he remarked, "that men here imbibe a liberal education from the very air breathed by Locke and Berkeley, surely we also may draw scientific inspiration from this air, not only breathed, but first explained, by Boyle, and Hooke, and Mayow."

Two evening lectures were delivered (1) by Dr. J. W. Gregory, on "Experiences and Prospects of African Exploration"; (2) by Prof. J.-S. Nicholson, on "Historical Progress and Ideal Socialism"; the lecture to the operative classes was by Prof. Sollas, on "Geologies and Deluges."

There was an overflowing attendance at the Sheldonian Theatre to hear Lord Salisbury's presidential address. It seems that numbers of volunteer helpers were swept aside, through the determined inrush of visitors, and thus were unable to perform their functions. An experience such as this will doubtless be borne in mind on the occasion of the meeting to be held next year.

T. E. JAMES.

Recent Developments in the Theory of Magnetism.¹

By Prof. C. G. DARWIN, F.R.S.

THERE have been several important discoveries made in the theory of magnetism in the course of the last two or three years, and we shall discuss some of these; but in order to appreciate them it will be well to begin with a description of the general magnetic

properties of matter. All magnets can be typified by the ordinary bar magnet, which has a north pole at one end and an equally strong south pole at the other. If such a magnet is cut in half, the north half grows a south pole at the section and vice versa. In consequence of this we do not take the magnetic pole as the working

¹ Discourse delivered at the Royal Institution on Friday, May 15

unit, but the magnetic dipole. We imagine that each molecule of the bar has north and south poles, and that they are ranged end to end, so that all the middle ones cancel out and leave a free north pole at one end and a free south at the other. The measure of a magnet is then taken, not as the pole strength, but as the *magnetic moment*, which is the product of the pole strength into the length. The moment of the whole bar is the sum of the moments of its molecules.

There are two chief ways in which magnetic effects exhibit themselves. The first is that shown by a compass when it twists round so as to point along the direction of the earth's field. There is another effect which is very important, and to be distinguished from it, which arises when the field is not uniform. Then one end of the magnet will be pulled more than the other is pushed, and so the magnet will experience a force moving it bodily—this may be either an attraction or a repulsion. The first effect is usually easier to exhibit, but we shall be more concerned with the second.

Under the influence of a magnet all bodies become themselves magnetic, but there are three quite distinct types of behaviour. A piece of iron becomes strongly magnetic with a south pole next the north pole of the inducing magnet. Iron, nickel, and one or two other substances have this property to a high degree, but there are many others, for example aluminium, which show it feebly. For all these it is about a hundred-millionth less, and so a different name is used. Iron, etc., are said to be ferro-magnetic, the rest are called para-magnetic. If a paramagnetic rod is put between the poles of an electro-magnet, it becomes itself a feeble magnet with north pole next to the south pole of the inducing magnet. There exist many other substances, for example copper, having the opposite property. Facing the north pole of the electro-magnet there appears a feeble north pole. This property is called diamagnetism. The measure of the two properties is called *susceptibility*, and is positive for paramagnetic and negative for diamagnetic substances. It is found by making experiments in non-uniform fields. A paramagnetic substance tends to move into the strong field, a diamagnetic out of it. So a bar hung between pointed pole pieces will twist round towards the points in the first case and away from them in the second.

Magnetic action is exhibited by electric currents, as is typified by the galvanometer and every ordinary electrical measuring instrument. Now, in science one cannot admit that two radically different things can produce identical effects, so we are forced to conclude that either the current is really a magnet, or the magnet is really a current, and the second is certainly the correct alternative. In each iron atom there is a current circulating, and this current gives rise to its magnetic moment. We shall see now how this explains dia- and para-magnetism, taking for simplicity the supposition that we are dealing with a gas.

Suppose that we surround a cylinder of metal by a wire and then send a current through the wire. The current causes a magnetic field along the axis. At the moment of making, an eddy current will be induced in the cylinder in the opposite direction, but the frictional resistance to the flow of electricity will destroy this quickly. But if there were no friction (as is actually the case at very low temperatures) this

current would persist indefinitely, and would exert a magnetic field weakening the other. This is exactly what diamagnetism does. So we say that the atom is something like a frictionless conductor. When a field is put on it induces opposing currents in the atoms, and these persist and exert a field opposing the external field.

We must next explain paramagnetism. We believe that every atom has the induced current of diamagnetism, but that this is overridden by a second property. Each atom of a paramagnetic gas has a magnetic moment, even when there is no field. If we could suppose them to be little bar magnets, they would swing to and fro in the presence of an external field, and would be oftener pointing down the field than up it. This would give an extra magnetic moment down the field and would be paramagnetism. Unfortunately the matter is not so simple as this, because the moment must be caused by a revolving electron, and this behaves quite differently. It may be likened to a top, which has the property of always moving at right angles to the direction in which it is pulled. So our atom will not go towards the field at all but will precess round it, and there will be no gain of magnetic moment in the direction of the field. In order to get this gain we have to allow for collisions between the atoms, for then the axes of the tops will be able to change, and will, in fact, have the tendency to point oftener towards than away from the field. The amount of the effect may outweigh the diamagnetism which is always present. The phenomenon shows a clear sign that it depends on collisions, for whereas diamagnetism is constant, paramagnetism depends on the temperature. When the gas is hot, the violence of the collisions makes nearly as many molecules point away as towards the field, but when it is cold the gentle collisions allow them nearly all to settle down along the field.

There is a most difficult point in the argument which is rather too abstruse to explain in detail. It turns on the proper way of taking the averages of the moments of the atoms. This must be carried out with the greatest rigour from dynamical principles. In the past many writers tried to make short cuts and obtained a variety of results. Some proved there could be no paramagnetism, some no diamagnetism, and some even that there could be neither. The essential point of the argument is that the atom must have somewhere the property of a top, which goes on spinning at the same rate however its axis may be altered. It must, so to speak, be able to remember for an indefinite length of time how it behaved when the field was first put on. At least that is how the matter stands on the classical theory. But, as we shall see later, there is definite experimental evidence which shows that the atom is only allowed to exist in a certain very limited number of states, and this rather eases the difficulty; for it need no longer remember its past history, but instead must conform to a rule, unexplained it is true, but in general conformity with other unexplained properties of matter.

The question arises as to whether there would be any way of observing the magnetic moment directly. Such a way was suggested by Stern about three years ago, and the experiment which he carried out in conjunction with Gerlach is certainly one of the most remarkable

of the present century. In a vacuum an atom of gas will go in a perfectly straight line until it hits the wall. If a source of atoms is in line with two fine slits, they will all hit the opposite wall in a narrow line. The atoms were obtained by boiling silver in a small furnace. Those which get through the slits strike the wall and stick there. Even after four hours nothing is visible on the glass, but there exist chemical methods of development whereby the invisible trace of silver attracts more silver from the developer and becomes visible. Now suppose that in their path the atoms encounter a non-uniform magnetic field. In the gaseous form the atoms of silver have a magnetic moment, and so they will experience a deflecting force. If the atoms were pointing arbitrarily in all directions, the character of the field shows that the fine line of the image should be spread out into a lens-shaped figure. What is in fact observed is quite different; the lens is there but it is hollow. The atoms are all pointing straight towards or straight away from the magnetic field.

This result would have been astonishing twenty years ago, but as a matter of fact the experiment was tried with a fairly strong expectation that it would turn out as it did. The quantum theory has illuminated many branches of physics, but none more than spectroscopy, and in particular it describes with complete success the influence of magnetic fields on spectra. According to this theory the atom is a very definite structure, and the definiteness extends not merely to size and shape, but also to its direction in space. The theory goes further and indicates that an atom ought to have a definite magnetic moment, which is called the "Bohr magneton," or in some cases a simple multiple or fraction of this. In silver the deflexion corresponds exactly to one magneton. Several other substances have since been measured, and most of the effects explain themselves on the same principles. Modern physical theory has to face a great many difficulties, and one of the severest is to explain how it is that half the atoms can point away from the field. Each atom evaporates in the furnace right outside the magnetic field and pointing in an arbitrary direction. As it enters the field, if it is to point away, it must gain energy, and there is nowhere from which the energy can come. This would have been a severe difficulty a few years ago, but dynamical toleration has grown recently, and it is becoming recognised as a probability that energy is only conserved on the average and not exactly.

The older calculations of para- and dia-magnetism depend essentially on assuming that the atoms can

point in any direction, and they go wrong if this ceases to be true. We know it to be untrue in Gerlach's experiments, and the question arises as to whether it is true in other cases. This is the subject of some very remarkable recent experiments by Glaser. The susceptibility of gases is very small and hard to measure unless the gases are compressed. Glaser has perfected the arrangements of one method of experiment to such a high degree that he could measure the effect for very low pressures. The principle of his experiment can be described by analogy with the question of buoyancy. If a body is weighed in air and in water, the difference of the weights measures the weight of the displaced water. If a different liquid is used, a similar weighing will give its density in terms of water. Glaser takes a light rod of some substance, actually a slightly paramagnetic glass, and suspends it in a non-uniform field. In a vacuum the field twists the rod round by a definite amount. If it is surrounded by a gas which is also paramagnetic, it will not experience so great a twist, because it will, so to speak, be partly floated by the gas. Similarly, if the gas is diamagnetic, it will be more twisted than in a vacuum. The effect is very small and by no means easy to obtain, but by measuring the amount of twist a value can be found for the susceptibility. The diamagnetism stays constant down to a fairly low pressure, and then changes over to a larger value—actually three times as great. The work is very recent, and the theory is still more or less unknown. Superficially the phenomenon is rather like that of Gerlach, but a little deeper consideration shows that no very close analogy can be drawn between the two cases.

It is natural to suppose that the collisions between the molecules are somehow responsible for reducing the susceptibility at high pressures; but there is great difficulty in seeing how it comes about, for it must be remembered that even at high pressures a molecule is in collision for only a small fraction of the time it spends between collisions. Moreover, though it might be possible to explain in this way a change of susceptibility, there seems no chance of getting a factor so great as three to one. No doubt there will soon be more experiments to help us. For example, much could be deduced if we knew how the curves varied for different temperatures; and it would also be most interesting to know how other gases behave, in particular the strongly paramagnetic oxygen. Unlike the work of Stern and Gerlach, Glaser's experiments do not seem to fit in with the general scheme of things, and so we may perhaps hope that they will lead to some surprising new developments in physical theory.

Obituary.

MR. W. E. CUTLER.

WE regret to have to record the death, on August 30, of Mr W. E. Cutler, the field palæontologist who was working in Tanganyika Territory for the British Museum on the Dinosaur-bearing beds near Lindi. Those who lead sheltered lives in Europe are sometimes apt to overlook the arduous character of the work on expeditions in tropical or arctic lands, where either endemic disease or extremes of temperature endanger human life, and we may venture to refer to an article in these columns on April 18, p. 573, of this

year, in which it was pointed out that the region in which these wonderful relics of an ancient fauna exist is pest-ridden to an unusual degree.

Mr. Cutler was a Londoner by birth, but emigrated to Canada with his parents at an early age. As a young man he became attracted by fossil collecting, and for some time it is believed worked in that wonderful natural museum which exists in Wyoming; later on he made some fine collections from the Cretaceous beds of Alberta and elsewhere. He served with the Canadian forces during the War, and then returned to

his adopted land to make collections for the University of Manitoba from the Ordovician beds of western Canada. He was about fifty years of age at the time of his death. He lived solely for his work, and had in the intervals of his collecting learnt a great deal about the anatomy of the creatures he sought for.

Brought up in a hard school, Cutler prided himself on going anywhere with a minimum of kit and the simplest of food, and it came as somewhat of a shock to him when he was equipped for the East African Expedition to find that his impedimenta contained tents, camp beds, mosquito nets and the like. He was impatient of such things, and inclined to look upon them as unnecessary luxuries which would need attention and therefore hinder his work. Maybe if he had more fully recognised the danger of the insidious *Anopheles*, he would have been spared to carry on his work.

Cutler's labours have been productive of fruitful results, and it is said that more than 600 bones have been collected, some of which have arrived, others being ready for despatch, and it will give some idea of the magnitude of the task when we learn that they will fill at least 120 cases. All these have been personally excavated and prepared for despatch by Mr Cutler with the help of a few untutored natives—no mean task! They have, of course, not yet been worked out systematically, but it has been determined that bones of both armoured and probably carnivorous dinosaurs as well as herbivorous species are among the specimens. Such an enthusiastic worker will be hard to replace, but the work must go on, for what has been achieved

only demonstrates the magnitude of the task and its importance. May this sad loss in the front line stimulate the public to support the expedition and enable it to continue with a staff much strengthened and supplied with every safeguard which the science of tropical hygiene can provide.

C. W. H.

WE regret to announce the following deaths:

Dr. Hans Bunte, emeritus professor of the Technical Highschool in Karlsruhe, well known for his work in connexion with the German gas industry, on August 17, aged seventy-seven years.

Prof. Ernst Erdmann, director since 1922 of the Institute for Applied Chemistry at Halle, on August 19, at Rättvik, Sweden, aged sixty-eight years.

Prof. Georg Klien, director for more than forty years of the East Prussian Agricultural Institute, in Königsberg, on June 23, aged seventy-six years.

Prof. Otto Lummer, director of the Physical Institute of the University of Breslau, whose investigations dealt with interference phenomena and with the estimation of the sun's temperature, on July 7, aged sixty-five years.

Dr. Rudolf Martin, professor of anthropology in the University of Munich and an honorary fellow of the Royal Anthropological Institute, on July 11, aged sixty-one years.

Dr. Mansfield Merriman, professor of civil engineering at Lehigh University from 1878 until 1907, who was a pioneer in the development of technical education in the United States and also was distinguished for his work on mechanics and strength of materials, on June 6, aged seventy-seven years.

Current Topics and Events.

SIR DANIEL HALL, in the course of his presidential address to the Conference of Delegates of Corresponding Societies at the Southampton Meeting of the British Association, appealed for their help in studying the antiquities of the land and of farming. He pointed out that the opportunities in local societies for the study of natural history and archaeology are rapidly becoming smaller, and even in such fields as botany and zoology the development of science is rapidly decreasing the sphere of activity available to the non-professional man. He therefore suggested that such individuals can profitably turn their attention towards recovering, before it is too late, the detailed agricultural history of the country. The Corresponding Societies can give invaluable help in discovering the original settlement of the land, the manors, the system of cultivation adopted before enclosure, and the date and method of enclosure. The need for this work has been made all the more urgent by the Law of Property (Amendment) Act of 1924, which practically does away with the manor as a legal entity, and by the recent sales and breaking up of many of the great estates. Title deeds and estate records in the hands of manor stewards, family solicitors and the like, may therefore become distributed and increasingly difficult to trace. In this connexion a request from a Society to be allowed to examine these records will carry far more weight than one from a private person. In addition, much

useful information could be obtained in some districts by a close study of vestigial physical traces of the old farming, and by the examination of field names referring, for example, to crops that have now disappeared. Again, the preservation for local museums of old farming implements would be a valuable activity of a local society. Apart from the intrinsic interest of this work, it would find a useful and highly desirable application in country schools. A series of parish maps showing the change in agricultural customs, distribution of land, vegetation, and so on, would provide excellent material for showing how, in response to physical and changing economic environments, the present farming system has slowly grown up from its simple beginning far back in the past.

AMONG the interesting exhibits shown in Section B (Chemistry) during the session devoted to the ignition of gases at the recent meeting of the British Association at Southampton were the photographs taken at Sheffield by Prof. Wheeler and Mr. O. Ellis on behalf of the Safety in Mines Research Board. By arranging a camera to open at regular short intervals, they have been able to photograph the successive positions occupied by flames produced by the firing of explosive mixtures of methane and air in closed spherical and cylindrical vessels. When the gas was fired by a spark in the centre of a glass sphere, the successive

images of the flame can be seen advancing uniformly so that the flame reaches the boundary simultaneously at all points; except for very slow flames, the effect of convection currents is inappreciable. Some of the photographs, first exposed when the flame had reached the walls of the vessel, show not only the ring of light outlining the circular image of the sphere, but also a re-illumination spreading outwards from the centre of the sphere. This after-burning affords a neat proof that the chemical action is not completed by the apparent passage of the flame through an explosive mixture. The illumination is due to pressure-waves reflected from the spherical surface meeting at the centre, and increasing the rate of the residual combustion. The phenomenon may be compared with the intense reflected waves sent back from the closed ends of short narrow tubes when the explosion-wave has not quite time to develop before the flame reaches the ends. Other photographs were shown in which the flames were started at the top, the bottom, and the side of the sphere. Such asymmetric ignition results in a retardation of the development of pressure and a lower maximum pressure compared with central ignition. When the gas was ignited in a cylinder, the flame progresses regularly until it touches the walls, then it appears to be squeezed slowly into the corners. The photographs have been reproduced in *Fuel in Science and Practice*, 1925, 4, 356.

THE Southampton meeting of the British Association came to an end on Wednesday, September 2, with a meeting of the General Committee, at which votes of thanks were passed to the mayor and corporation, local committee, officers, and all who had contributed to its success by their support and hospitality. At the meeting of the General Committee held on August 28, a deputation from Leeds attended to invite the Association to hold its meeting there in 1927, and the invitation was cordially accepted. The date of the Oxford meeting next year, at which the Prince of Wales will be president, is to be August 4-11. The following vice-presidents of the Association nominated from Oxford for the Oxford meeting have been appointed: The Chancellor of the University the Vice-Chancellor of the University, the Mayor of Oxford, the Lord Lieutenant of Oxfordshire, the Bishop of Oxford, the Dean of Christ Church, Sir Charles Sherrington, Lord Valentia, Dr. Gilbert C. Bourne, Dr. G. Claridge Druce, Prof. E. B. Poulton, Mrs. G. H. Morrell, Sir Arthur Evans, Prof. H. H. Turner, and the Principal of University College, Reading. The local officers for the meeting are: *Treasurer*, Mr. B. Rowland Jones; *Secretaries*, Dr. F. A. Dixey and Brigadier-Gen. H. B. Hartley. The new members of Council of the Association are: Prof. A. L. Bowley, Dr. H. H. Dale, Sir Richard Gregory, Prof. T. P. Nunn, and Prof. A. O. Rankine.

POPULAR interest in natural history is on the alert. The records of museums, popular lectures, public libraries, press articles and natural history publications generally, even the upshoot of the "fundamentalists," all show that interest has been aroused

in life and its workings. Here are evidences which the man of science cannot afford to ignore, for a widespread knowledge of the methods and discoveries of science must result in a fuller appreciation of scientific method and in the formation of a mass opinion which will thrust new power into the hands of the scientific worker. But the position also demands that science in its popular presentation shall be progressive. The day of the simple chronicle of the obvious has passed, and it is needful that the plain man should learn something of the more profound relationships and interpretations which now engage the investigator. Further, the people cannot safely be left to gain their impressions of the aims and conquests of science from the cheap trifles of the dilettante; the simple rendition of the subtleties of modern research, whether it be in the written word or in the museum exhibit, demands the application of the trained and fully stored mind.

BECAUSE of these things "The New Natural History," by Prof. J. Arthur Thomson (London: George Newnes, Ltd., 1925. To be completed in about 20 fortnightly parts, 1s. 3d. net each part), deserves a warm welcome. The first part, which has recently been received, suggests that the work is to take the form of a series of short unrelated essays dealing with various aspects of the manifestation of life: in the present 43 pages are compressed brief accounts under the headings of man's relations with other living creatures, the web of life, animal behaviour, the ways of monkeys, the beauty of life, the story of the bower-bird, everywhere there are fitnesses, everything in the light of its history, the hand of the past. In view of Prof. Thomson's own previous work and of the best popular natural history of the present day, the treatment is not strikingly "new," but it is new in the sense that it discards the stilted systematics of the past and emphasises the trend of modern zoology towards a fuller appreciation of the biological significances of structure, habit, and development. The work is to be completed in about twenty fortnightly parts. Should it share the success which met the earlier "Outline of Science" in Great Britain and in the United States it will exercise a wide influence in moulding popular knowledge of the attainments of scientific investigation of animate nature.

THE fourth autumn lecture to the Institute of Metals was delivered on September 1 by Sir John Dewrance on "Education, Research, and Standardisation." Using the word "education" in its broader meaning of education of the human race, Sir John emphasised the superiority of scientific method and of wisdom over mere knowledge, and asked for greater appreciation of those who have discovered new truths and made them available to mankind. Men with original minds should be spared from the necessity of earning a living by doing inferior work, but private benefactions for the furtherance of research being still inadequate, although increasing, the assistance of the State is imperative. After reviewing the main activities of the Department of Scientific and Industrial Research, and, in particular, those of the

National Physical Laboratory, Sir John Dewrance discussed the meanings of the words research, discovery, and invention, pointing out how closely they are interwoven, and urging a wide acceptance of "research" so as to include such activities as the designing of a new type of submarine, or the devising of a new method of production in a factory

WITH regard to the use by Sir John Dewrance of the word "research" to cover historical studies, it may be pointed out that the business of the historian is not, strictly speaking, to discover new facts but to resurrect old. It is true that he uses the scientific method and, like the investigator of Nature, frames views or hypotheses to correlate observations and immediate inferences from them, but in view of the circumstance that, although his interpretation may be new, his facts are necessarily old, there is a distinct difference between them and creative scientific research. Sir John Dewrance proceeded to describe the enormous amount of work involved in devising standards. The British Engineering Standards Association, formed in 1901, is controlled by a main committee which presides over 400 sub-committees of engineers and other experts who give their labour gratuitously; and it is pleasing to hear that in a recent letter the Prime Minister expressed his appreciation of the valuable work done by the Association and his confidence in the application of its methods to the study of production costs, which is one of the most pressing industrial problems of the day. In Sir John Dewrance's view, the character of virtue is best seen in the life of an intellectual man devoted to the service of truth. The status of the discoverer and research worker is being gradually raised, and he hoped that his lecture would hasten progress. "All who have benefited by knowledge should feel it a duty to do something for the acquisition of further knowledge"

IN the early hours of September 3, the great United States airship *Shenandoah* was destroyed by a storm which broke the vessel into three pieces. The *Shenandoah* was noteworthy in that its gas-cells were filled with helium instead of hydrogen, and details of its structure were given in an article in NATURE of March 1, 1924, p. 313. It would appear that on September 3 the airship was travelling at an altitude of about 3000 ft. near Cambridge, Ohio, and according to a telegram to the U.S. Navy Department by Commander C. E. Rosendahl, the senior surviving officer of the airship, a mild storm was followed by a sudden line squall which caused enormous and uncontrollable angle strains and a rapid vertical ascent. This resulted in the ship's structure breaking when it got to a height of about 7000 ft. It is suggested in a message from the New York correspondent of the *Times* that the sudden rise of the airship caused undue expansion of the helium containers, straining the strut wires and girders and cracking the framework. Capt. Anton Heinen is quoted as stating that the disaster was indeed due to this cause, and that the number of safety-valves in the *Shenandoah* were

insufficient to permit of the rapid release of gas necessary when a sudden ascent is made

THE following Royal Commission has been appointed to inquire into and report upon the economic position of the coal industry in Great Britain and the conditions affecting it, and to make any recommendations for the improvement thereof: Sir Herbert Samuel (chairman), recently High Commissioner in Palestine, Sir William Beveridge, Director of the London School of Economics, General the Hon. Sir Herbert Alexander Lawrence, a managing partner of Glyn, Mills, Currie and Co., and Mr. Kenneth Lee, chairman of the British Cotton Industry Research Association and of Messrs. Tootal Broadhurst Lee and Co., Manchester. The following are to act as expert assessors: Mr. William Brace, Chief Labour Adviser to the Mines Department, Dr. Walcot Gibson, formerly of the Scottish office of the Geological Survey of Great Britain, Major H. M. Hudspeth, one of H.M. Divisional Inspectors of Mines, and Dr. C. H. Lander, Director of Fuel Research, Department of Scientific and Industrial Research. The secretary of the Commission is Mr. C. S. Hurst, Assistant Under-Secretary, Mines Department.

A PROVISIONAL programme has been issued of the second conference of the Association of Special Libraries and Information Bureaux to be held at Balliol College, Oxford, on September 25-28. The first session will be opened by Dr. R. S. Hutton, chairman of the conference, who will describe the present position of the Association, and in the general discussion which is to follow, Mr. A. E. Twentyman and Prof. F. E. Sandbach will speak. On the following day, the morning session will be divided between two discussions, on the special library movement in America and the Institut Internationale de Bibliographie, Brussels, respectively, while the afternoon will be devoted to papers on abstracting, cataloguing, indexing and filing. A discussion in the evening will show the relation of special libraries and information bureaux to the Press. Meetings will be held on Sunday, September 27, in the morning and evening, at which the relation of special libraries to patents, science, medicine, education, transport and other aspects of modern life will be discussed.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: The Dutton memorial professorship of entomology in the University of Liverpool—The Registrar, The University, Liverpool (October 1). Two chemists at the Naval Ordnance Inspection Centre, Holton Heath, Dorset—The Secretary of the Admiralty (C.E.), Whitehall, S.W.1. A biologist at the Kirton Agricultural Institute, Boston, Lincs.—The Principal. A cancer research worker at the Radium Institute—J. C. Mottram, Research Laboratories, The Radium Institute, 16 Riding House Street, W.1. Lecturer in mechanical engineering—Agent-General for Western Australia, Savoy House, Strand, London, W.C.2.

Research Items.

THE MAYAN CALENDAR.—An interesting contribution to the discussion of the calendar of the ancient inhabitants of Central America and its possible correlation with Christian chronology is made by Mr. J. E. S. Thompson in *Man* for August. Spinden, in his new scheme of correlation, has made the Mayan New Year Day fall on the winter solstice, which he says was arbitrarily chosen to initiate the calendar. But the names of the Mayan months appear to contradict his theory. Although data relating to the annual routine in agriculture of the pre-Spanish Maya are absent, it is justifiable, in view of their innate conservatism, to assume that modern Mayan customs give a fairly clear idea of the routine of their ancestors. When the agricultural operations are taken month by month, it is found that each of these is faithfully represented by the names of the month in the calendar. For example, in December and January the virgin bush is cut down, the scrub is left to dry until May, when it is burnt, whereupon the Mayans leave their villages to take up their residence in their *Mulpas* (allotments). Then come the heavy, late spring rains, softening the ground, and sowing follows. In the Mayan calendar as given by Landa, *Mol* corresponds to December 12, meaning to pile or collect together, i.e. the brushwood was piled. *Ceh* or *Cel*—roasted, March 2, refers either to the burning of the brushwood or the condition of the soil after drought. *Muan*, May,—showery. *Pax* (May-June), to take possession, referring to the removal to the *Milpas*, and so on. Any correlation which does not conform to the naming of the months, such as Spinden's in making *Cumhu*, the sowing season, and *Pop*, maize leaves, mid-winter instead of June and July, must be rejected.

PALÆOLITHIC MAN IN MORAVIA.—The third instalment of the Abbé Breuil's survey of palæolithic sites in Central Europe which appears in Pt. 3-4 of Vol. 35 of *L'Anthropologie* deals with the Moravian caves, of which the most important are Kostelík and Kulna. At Kostelík, which is in the neighbourhood of Brno, the fauna is that of the mammoth and the reindeer. Notwithstanding the absence of stratigraphical evidence, some of the stone implements can be attributed with some certainty to the Acheulean-Mousterian; others belong to the Aurignacian and beginning of the Solutrean; others again are of a generalised upper palæolithic type and are to be assigned with some probability to the Magdalenian. Certain remarkable objects made from the jawbones of horses, which have been described ineptly as carvings representing fish, are in reality a kind of ornamented knife in which the curved part of the jaw without teeth has been utilised to form a handle. Both sides of the blade and handle are closely covered with an ornamentation of parallel curved lines alternating with short strokes and big dots. In some cases they are combined to form a very simple decorative motif, such as a group of chevrons, while in one case this may be a sketch of an animal's head. The remainder of the bone implements are Magdalenian, probably of various periods. A postscript describes a small statuette of a mammoth in clay found near Untertarnitz in 1924.

EYE FATIGUE.—In the *Journal of the Franklin Institute* (August 1925), Mr. Percy W. Cobb and Mr. Frank K. Moss give the results of some experimental work on eye fatigue in its relation to light and work. The problem of lighting is one of outstanding importance in industrial work; when work can be performed by daylight the problems are relatively simple, but as soon as artificial light has to be used

new factors intervene. With the higher intensities of illumination people are apt to complain of eye fatigue. The laboratory experiments described in this article were an attempt to study the effect produced by visual operations under different intensities of illumination. An ingenious test was devised as a means of fatiguing the eye—and incidentally the attention—and the effect of the different intensities was measured by comparing the changes in the muscle balance of the subject before and after the test. The test itself, worked for 30 minutes, did affect the muscle balance significantly, but the change in the intensity of the illumination showed no significant difference either with regard to the amount of work done or the effect on the eye. The conclusion, though, cannot be expressed by the general statement that the higher intensity was in no way harmful or tiring to the eyes of the worker; all that can be said is that, under these conditions, no appreciable effect could be observed. The eye fatigue cannot be estimated apart from the effect of attention, and industrial conditions introduce still more complications.

INSECTS OF THE SWISS NATIONAL PARK.—Volume 60 (1924) of the *Denkschriften* of the Swiss Natural Science Society, consists entirely of the second and third instalments of the results obtained under the Commission appointed by the Society for the study of the fauna of the Swiss National Park in the Lower Engadine. The Hemiptera and the Collembola are dealt with in the volume before us. Dr. Hofmann began his special investigation in 1918 in company with Dr. R. Menzel, but lost that valuable colleague on his being called away for special entomological work in Java. His account of the Swiss Hemiptera deals with the Heteroptera and the Cicadine group of the Homoptera. Including previous records, and not adhering strictly to the confines of the National Park, he finds the list of Heteroptera to comprise 113 genera, 181 species and 6 varieties, while the Cicadinae number 81 species and 15 varieties distributed among 28 genera. The most interesting conclusion arrived at is that the Hemiptera of the Lower Engadine are somewhat southern in character, and have a marked affinity with the fauna of the South Tyrol. Dr. Handschin's researches into the Collembola of the National Park have been very fruitful. He adds to the list of 65 hitherto recorded Swiss species no fewer than 30 species, of which 7 are new to science. Moreover, the abundance of his material has enabled him to show that several forms regarded as specifically distinct are in reality only colour variants. Thus he is led to suppress *Entomobrya lanuginosa* and *E. nicoleli* with its two varieties *muscorum* and *obscura*, all of which he finds to belong to the very variable species *E. nivalis*. Both authors give full details of horizontal and vertical distribution, and the plates are adequate. Altogether this instalment of the results of the Commission forms a handsome volume.

THE COLEOPTEROUS FAMILY BRENTHIDÆ.—*Indian Forest Records* (Entomology Series), vol. 11, Part iv., 1925, is devoted to studies on some Indian beetles of the family Brenthidæ. Herr Richard Kleine describes a number of new genera and species from British India and the neighbouring regions, bringing up the total number of known members of the family to 240 species. Dr. C. F. C. Beeson contributes an article on the biology of the family and its relations to forestry. This paper is the most important yet published on the subject and adds very considerably to what little was previously known. The family is divisible into two

groups—(a) phytophagous, and (b) myrmecophilous, the latter only containing a few species. As regards group (a) Dr. Beeson's observations suggest that the Indian species (at any rate) are true wood-borers in the larval state and that their habitat is normally in felled or fallen timber and not in living trees. The adult beetles occur gregariously between the bark and wood of trees that have been attacked by bark and sapwood-boring larvæ (mainly Longicornia). The myrmecophilous species include symphylines living in association with ants, while others are robbers. Mr. J. C. M. Gardner describes the larvæ of two species of Cerobates and the pupa of *Cyphagogus corporaalii* Kleine. The larvæ show characters common to the Rhynchophora, e.g. their curved form, the vestigial antennæ, the continuity of the mentum and prothoracic cuticle, etc. The presence of evident though minute thoracic legs is not incompatible with these affinities since many curculionid larvæ exhibit reduced ambulatory tubercles.

INDIAN LIMNÆIDÆ.—The last memoir from the hand of the late Dr. Annandale forms a revision of the recent Indian Limnæidæ, in which H. S. Rao collaborated (Records Indian Museum, vol. 27, Part 3, May 1925). The authors have offered this paper as a means of identifying the species of Limnæa found in the Indian Empire. They have had the advantage of studying the largest collection of shells and of material preserved in spirit ever accumulated from any oriental country, and they have had good opportunities of noting the range of variation. They discuss the characters of the jaws, radulæ, shell, and genitalia, and after concisely describing 21 species and their "forms," they provide a tabular key to the living species known from the Indian Empire and its immediate frontiers and a table of measurements of their shells. In Part 1 of the same volume is an obituary notice of Dr. Annandale and a list of his publications, which occupies 21 pages; it indicates the extraordinary range of his interests and the activity of his mind and his pen.

THE BOGHEAD COALS.—The United States Geological Survey has published an interesting paper (Professional Paper 132-I), by Reinhardt Theissen, on the origin of the Boghead coals. This paper is a careful study of that group of coals which passes into true coal on one hand and into shale on the other, including, therefore, the substances usually spoken of as bituminous shales, oil shales, cannel coals, etc. The author shows that the yellow bodies characteristic of boghead coals are algæ of a somewhat unusual form; the name *Elæophyton* has been suggested for this organism, and its structure has been worked out in considerable detail. The paper is all the more interesting because it is practically contemporaneous with the work by Prof. Jeffrey of Harvard University, lately noticed in these columns, who discusses these bodies at considerable length, and proves quite definitely to his own satisfaction that the bodies in question are spores and not algæ. It is, however, clear that Prof. Jeffrey knew nothing of Mr. Theissen's work.

INDIAN METEOROLOGY.—The meteorology of India was dealt with by Sir Gilbert T. Walker, professor of meteorology, Imperial College of Science and Technology, in a paper read at the Royal Society of Arts on May 8, and published in the Society's Journal of July 31. As Sir Gilbert was chief of the Meteorological Department in India for more than twenty years, and until quite recently, many points of considerable interest were referred to. The characteristic feature of the south-west monsoon is

explained, and the three weeks' journey of the air over the sea before it reaches India is said to afford time for air dry at its origin to become saturated with moisture to a considerable height, which is necessary to supply such rainfalls of 30 to 40 inches in a day, which occur in the western ghats and the corresponding hills near the Burma coast, combined with moderately heavy rain inland. Work carried on for the last forty years by Blanford and Eliot, and later by the author of the paper, with the view of forecasting the monsoon rains by the assistance of data in various parts of the globe, is explained. The difference between the air motions producing abundant and scanty rainfall is associated with marked differences in the conditions over a large part of the earth's surface. Abundant Indian rains are associated with low pressure in India, Java, Australia, and South Africa, and with high pressure in the Central Pacific and South America. The warning for storms at sea is assiduously carried out, and warnings are issued of the danger of sunstroke or heat apoplexy when the wet bulb temperature approaches 85° F.

A LABORATORY OZONISER.—A laboratory ozoniser, capable of yielding high concentrations of ozone (15 per cent.), is described by L. I. Smith in the July issue of the Journal of the American Chemical Society. The capacity of the ozoniser is more than 4 gm. of ozone per hour. The apparatus consists of three modified Brodie tubes, made of soft glass, connected in series and mounted in a large battery jar. All connexions which come in contact with ozone are arranged so as to be made through mercury seals. The battery jar is filled with distilled water, and serves both as an electrode and for cooling purposes. Owing to the high voltage used (about 8000) the resistance of the water is negligible, and thus there is almost no heating effect; a metallic cooling coil, however, is also immersed in the jar. The electrode inside the tube consists of mercury. Some observations on the action of various reagents on ozone are also recorded. These fall into two groups: (1) substances having only a very small effect, e.g. water, concentrated sulphuric acid, phosphorus pentoxide resublimed in oxygen, and (2) those having a great effect, destroying much or all of the ozone, such as ordinary phosphorus pentoxide and 5 per cent. sodium hydroxide solution.

DECOMPOSITION OF SULPHURYL CHLORIDE.—A paper by D. F. Smith in the July issue of the Journal of the American Chemical Society records some observations on the thermal decomposition of sulphuryl chloride. This is a first-order homogeneous gas reaction. Only one other such reaction is known, namely, the thermal decomposition of nitrogen pentoxide, investigated by Daniels and Johnston (1921). The data obtained for sulphuryl chloride fit the theoretical equations put forward by Trautz and Bhandarkar (1919). No theory of reaction rate yet proposed, however, fits in with the observations made in both of these reactions, so that none of these theories is of general application.

HYDROBROMIC ACID IN ACIDIMETRY.—The composition of an aqueous hydrochloric acid solution which boils at a constant temperature is sufficiently definite to permit its use as a standard solution in acidimetry (Hulett and Bonner, 1909). D. T. Ewing and H. A. Shadduck have published a paper in the Journal of the American Chemical Society for July, showing that hydrobromic acid solutions may be used for the same purpose. The constant-boiling acid boils at about 125° (760 mm.) and is 5.9061 N by weight. It contains 47.795 per cent. HBr.

Mosquito Control.

OPENING OF A NEW INSTITUTE AT HAYLING ISLAND.

A NEW phase in the control of the mosquito problem was reached last week when members of the Section of Zoology of the British Association attended the opening of the British Mosquito Control Institute, which has been founded and equipped by Mr. J. F. Marshall in his own grounds at Hayling Island, Hants.

The new building (Fig. 1) occupies two stories and includes a demonstration museum, a laboratory, drawing and record offices, photographic rooms, a library, and a mechanical workshop. There are also a number of smaller rooms designed for research students. It already contains a wealth of material for mosquito study not available elsewhere, and historical records of how the mosquito has been successfully combated on the island.

The formal opening, which took place on Monday, August 31, was presided over by Sir Richard Gregory, chairman of the Council of the new Institute. As a result of the preventive work undertaken, which has

consisted largely of draining the inter-tidal areas, Hayling Island, which formerly was infested with "salt-marsh" mosquitoes, has now been practically cleared. In introducing the subject, the chairman pointed out that in many parts of the world the question was whether the

mosquito or man should survive. It was, he said, one of the glories of British science that much of its best work had been done by men who were not professional workers but had studied Nature simply because of the desire to gain knowledge, and without any ulterior motive. Mr. Marshall had been responsible for work of that kind, and the result of it was the building that was about to be opened, the British Mosquito Control Institute.

Sir Ronald Ross, in opening the Institute, described his own experiences at Hayling Island some three years ago. He had, he admitted, been sceptical as to the accusations made against *Ochlerotatus detritus*, the salt-water mosquito. Mr. Marshall, however, had convinced him by taking him to a part of his garden and inviting him to observe the insects flying about in broad daylight. In the course of his observations, Mr. Marshall had proved his point by directing his attention to the fact that three of the insects were simultaneously extracting blood from the back of his neck. Sir Ronald Ross pointed out that when he began work on the mosquito there was not a book or a good article dealing with the mosquitoes in India. Much is now known, but, in addition to knowledge, energy is necessary for acting upon it. What has been done in the Panama, at Ismailia, and in the Federated Malay States is only a beginning. He insisted on the importance of controlling not only the

mosquitoes but also all those dangerous and unpleasant pests that prey on man and on his crops and herds. It is ridiculous that while man dominates the earth, the sea and the air, he should continue to be the prey of bacilli and even die from such contemptible things as colds in the head and mosquito bites. Improved medical and sanitary science and administration have, in the last eighty years, increased the average length of human life in Great Britain by about fifty per cent., yet men still die of many diseases which will one day be conquered. Sir Ronald Ross pleaded for the expenditure of a million pounds a year on medical research so as to accelerate the conquest of disease. Such a sum would be trivial compared with the money now spent on tobacco, alcohol, and entertainment, without taking into account what is spent on education, armaments, and the "dole." While the work of the new Institute is to be general rather than medical, it will unquestionably

keep the sanitary applications of mosquito control within range of its vision. The knowledge gained in the Institute will facilitate mosquito control in every region of the earth, and it is certain that the day will come when the fertile tracts now ravaged by king Malaria and king Mosquito will

FIG. 1.—The British Mosquito Control Institute.

be laid open to civilisation. This happy result will, however, only be attained by more thought, by more research, and by a firmer determination to make the most of the beautiful world in which we live.

A vote of thanks to Mr. Marshall was proposed by Mr. C. Tate Regan and seconded by Col. James, of the Medical Department of the Ministry of Health. The Ministry, he said, greatly appreciates the good work done by Mr. Marshall. Col. James emphasised the importance of voluntary assistance given to the Government, and said that it is on this that the success of public health administration largely depends. He promised on behalf of the Ministry that it would watch the working of the Institute with great and, he hoped, helpful interest.

The ceremony concluded with a few words of thanks from Mr. Marshall, and it was announced that the composition of the Council of the Institute is as follows:—Major E. E. Austen, Dr. Andrew Balfour, Mr. F. Balfour-Browne, Sir James Crichton-Browne, Dr. H. Eltringham, Sir Richard Gregory, Col. S. P. James, Dr. G. A. K. Marshall, Prof. H. Maxwell Lefroy, Prof. E. B. Poulton, Sir Ronald Ross, Dr. Hugh Scott, Sir Arthur E. Shipley, Prof. Sir William Simpson, and Dr. C. M. Wenyon. The Trustees are Sir Richard Gregory and Mr. L. W. North Hickley, and the honorary director, Mr. J. F. Marshall.

Glutathione.

THE isolation by Hopkins of glutathione, the dipeptide of cysteine and glutaminic acid, was a definite advance in our knowledge of the processes of oxidation and reduction in living cells. The compound was found to exist in two forms, the reduced and the oxidised; the latter consists of two molecules of the former united by means of the sulphur atoms of their cysteine portions after the loss of two atoms of hydrogen. The oxidised form thus acts as a "hydrogen-acceptor"; in the reoxidation of this reduced form it is probable that active oxygen is set free for oxidation processes in the cell, oxygen also acting as the "hydrogen-acceptor"; whether the compound was present in the oxidised or reduced form seemed to depend largely on the hydrogen-ion concentration. It was suggested by Quastel, Stewart and Tunncliffe that the dipeptide was formed by the linkage of the amino group of cysteine to that carboxyl group of glutaminic acid which is furthest away from its amino group; they based their conclusion on a study of the breakdown of the molecule in various directions.

Stewart and Tunncliffe have now confirmed this view by preparing glutathione synthetically and finding it identical with the natural product (*Biochem. Journ.*, 1925, vol. 19, p. 207). Two methods were employed: in the first, glutaminic acid was converted to hydantoinpropionic acid, and the latter then converted to the acid bromide with phosphorus tribromide and coupled with cystine dimethyl ester hydrochloride. The hydantoin ring was opened by boiling with calcium hydroxide, and the resulting compound, probably a uramino-acid, converted to the dipeptide by treatment with nitrous acid in slight excess of the amount necessary to remove one nitrogen atom. The dipeptide was isolated from the products of the reaction by means of the mercuric sulphate compound. The glutathione formed agreed with the natural product in all its properties except that its rotatory power was considerably less. This is probably due to racemisation during the formation and opening of the hydantoin ring. This result led the authors to their second method of synthesis: by acting directly on glutaminic acid with phosphorus tribromide, the acid bromide was formed in which the bromine replaced the hydroxyl group in the carboxyl furthest from the amino group. The acid bromide was coupled with cystine dimethyl ester and the glutathione isolated as in the previous method. The compound was found to be completely identical with the natural glutathione.

The amounts of the dipeptide occurring in tissues are very small; quantitative determination by actual isolation of the substance can only lead to approximate results owing to the losses which are bound to occur. Tunncliffe has elaborated a method which is both quicker and probably more accurate (*Biochem. Journ.*, 1925, vol. 19, p. 194). The tissue is ground with sand and 10 per cent. trichloroacetic acid and filtered. The filtrate is titrated with $N/100$ iodine solution, the reduced form of glutathione being thereby oxidised. The end-point is judged by the use of sodium nitroprusside as an external indicator, with which the reduced glutathione forms a purplish colour. The method estimates the —SH groups in the extract: glutathione is the only known substance present which will give the reaction, since there is no evidence that cysteine exists in the free state in the tissues normally. Most of the glutathione appears to be present as the reduced form in the cells. Skeletal muscle of the rat or rabbit contains about 0.03 to 0.04 per cent., and liver 0.2 to 0.25 per cent.; yeast

contains about the same percentage as liver; it is completely absent from blood. The values obtained thus are three to five times greater than the amounts actually isolated.

The product obtained from tissues has been found to contain small quantities of iron: Harrison has determined its amount and obtained a value of 0.6 per cent. (*Biochem. Journ.*, 1924, vol. 18, p. 1009). Now the reduced form of glutathione undergoes spontaneous oxidation in air; recognising that iron frequently acts as a catalyst in oxidations, Harrison prepared a pure glutathione and examined its rate of oxidation in air. The uptake of oxygen was much slower than in the case of the impure preparation: the author considers that this may be due to traces of catalysts which have escaped removal. As with the impure compound, cyanides inhibit this uptake of oxygen, probably by forming a compound with the iron.

The oxygen uptake in these cases, including that of pure glutathione, is a linear function of the time over a large part of the course of the reaction: this is probably due to the fact that the rate of oxidation depends on the amount of dissociated ionised iron present; the sulphhydryl group can lose its hydrogen more quickly than oxygen can be prepared to receive it. Increasing amounts of cyanide decrease the rate of oxidation by decreasing the amount of ionised iron present. On the other hand, when relatively large quantities of iron are available the rate of oxygen uptake decreases continuously, since excess of active oxygen is present throughout and the amount of the sulphhydryl compound becomes the limiting factor and its concentration progressively decreases with its oxidation.

The inhibiting effect of cyanide is less marked in the presence of organic iron, for example hæmatin, and in correspondence with this, Harrison has found that cyanide has a less marked effect in reducing the oxygen uptake of glutathione in the presence of a thermostable preparation of muscle tissue, which has the power of reducing the oxidised form of glutathione to the sulphhydryl compound.

Further light has been thrown on the mechanism of the action of glutathione in the oxidation processes of tissues by some recent experiments by Tunncliffe (*Biochem. Journ.*, 1925, vol. 19, p. 199). The reduction of the oxidised form by the tissue preparation in the absence of oxygen is rapid for the first three hours and complete in about five hours: only a certain quantity can be reduced by any given tissue preparation, this amount being the measure of the labile hydrogen of the tissue. The same tissue will reduce a similar quantity of methylene blue. The nature of the buffer salts and the reaction of the medium have no influence on this reduction. On the other hand, the reverse change, the oxidation of reduced glutathione, proceeds more rapidly in a slightly alkaline medium than in an acid medium. In the presence of oxygen, the tissue will reduce the glutathione, which will forthwith become oxidised again and the process will only cease with exhaustion of the labile hydrogen of the tissue or of the oxygen supply.

If, however, the amount of oxygen actually taken up is measured, it will be found to exceed considerably that necessary to oxidise the reduced glutathione formed by the tissue: the excess is considerably greater in the absence of phosphate ions. Hence concurrently with the oxidation of the glutathione, oxidation of some other substance must be taking place, and Tunncliffe considers it probable that this is of the

nature of an unsaturated fatty acid, since Meyerhof has shown that the oxidation of linolenic acid is accelerated by the simultaneous oxidation of a sulphhydryl group present at the same time. Thus the oxidation of the fatty acid depends on the presence of the reduced glutathione, which in turn is formed by

the "hydrogen donators" of the tissues. When oxygen acts as a "hydrogen-acceptor," removing the hydrogen from the reduced glutathione which is thereby oxidised, part of the oxygen becomes activated and available for the oxidation of other substances present in the cell.

The Royal Observatory, Edinburgh, and Accurate Measurements of Time.

THE record of the work done in 1924 at the Royal Observatory, Edinburgh, recorded in the annual report of the Astronomer Royal for Scotland, Prof. R. A. Sampson, is of supreme importance to those interested in the accurate measurement of time.

For some years Edinburgh has taken the lead in this subject, and Prof. Sampson's papers before the Royal Society of Edinburgh and the Royal Astronomical Society on the performance of his clocks have been followed with keen interest in the observatories of the world. His three first-grade clocks are the Riefler No. 258, which, we understand, is one of the best turned out by the famous Munich firm; Leroy No. 1230, which is a duplicate of those at the Paris Observatory used in connexion with the time transmission from the Eiffel Tower; and Shortt No. 0, the original Free Pendulum of the Synchronome Co.

By means of an oscillograph and micro-chronograph, which resembles a cinematograph camera, Prof. Sampson's clocks are in effect *put under a microscope*, that is to say, their performance is observed and automatically recorded each day to an accuracy of one thousandth part of a second, a method which Prof. Sampson says "rarely fails to show when one or other of them has changed rate by as much as .01 sec." The daily comparison, he continues, demonstrated a decided superiority in the rate of clock Shortt; indeed the other two were scarcely able to serve as a check upon it. Therefore, with the view of carrying time work to the limit that the appliances will allow, a second model of the clock (Shortt No. 4) was installed in January in one of the vacant clock cells in the basement. The connexions for temperature control are the same as in the other cells. The original clock of these series (Shortt No. 0) which was erected here for trial by Mr. Shortt in 1923, and has shown such remarkable going, has been generously presented to the Observatory by the Synchronome Company Limited, in association with whom Mr. Shortt had prepared his model. Briefly, it may be said the only discernible faults in the going of Shortt No. 0 are a small temperature coefficient showing when an accident disturbs the temperature control of the cell, and a minute leak in the case, which has not been located.

Prof. Sampson's investigations in recent years have

focussed attention upon the lack of precision in transit observations, upon which, of course, all time determinations are based. Instrumental errors in the transit circle telescope have always been carefully measured and allowed for. They take a prominent part in the somewhat complex process of smoothing the clock rates. In the race for accuracy, the precision of the clock and of the means of comparison by wireless time signals have outrun the precision of transit observations.

Radio telegraphy has enabled distant observatories to compare their times with great precision, thanks to the rhythmic signals or "time-vernier," and they are found to disagree by amounts which, though they may appear trivial to a layman, are of considerable importance in an exact science such as astronomy. Astronomers have indeed been considerably perturbed at their lack of agreement, and Prof. Sampson had set himself the task of searching for the cause of the error which has been found to occur in time determinations at all observatories.

Prof. Sampson now makes the definite statement that "owing to improvements in the clock and chronograph system in this Observatory, and in receiving apparatus for W.T. signals from other observatories, it has proved possible to bring this investigation to an issue. It has been found that during the whole of 1924 the whole of the large erratic or systematic errors are removed if the level error, determined as usual by the mercury bath, is rejected, and the observations reduced instead by an azimuth error derived from one of the collimators, in combination with the usual observations of polar stars. The implications of this result are of high interest and importance to astronomers and will be pursued."

Referring later to his automatic records of the numerous W.T. signals, Prof. Sampson says, "the comparison of time determined at this observatory with the same determined elsewhere exhibits features of the sub-systematic character that had been noted in previous years, though each observatory had cleared its determinations of all known errors. As remarked above, the source of these discrepancies appears now to be located, at least so far as the observatory is concerned."

F. H.-J.

World Meteorology and Long-range Forecasting.¹

THE possibility of seasonal forecasts in India was first investigated by H. F. Blanford about 1876, using only the snowfall in the Himalayas. As the research proceeded, it was found necessary to consider conditions farther and farther away, until in the hands of Sir Gilbert Walker it developed into an investigation of the inter-relationships of weather in all parts of the world. A chart of the average barometric pressure over the globe shows a number of more or less permanent areas of high and low pressure; for example, the Azores high and the Icelandic low. In these areas the variability of pressure reaches a

maximum, and they are accordingly termed "centres of action"; the pressure changes of intervening places, such as the British Isles, are dominated by those at the centres of action.

Sir Gilbert Walker has realised that these "strategic points" offered the best chances for an attack on the problem of long-range weather forecasting, and has studied in great detail the relations between twenty different centres of action. In "Correlation in Seasonal Variations of Weather," Part 8 (Memoirs of the Indian Meteorological Department), published in 1923, he laid down the groundwork of a theory of world weather and outlined the mechanism by which variations in one part of the world are transmitted to other parts of the world a few months later. The

¹ "A Further Study of World-Weather. Applications to Seasonal Forecasting in India." By Sir G. T. Walker. (Memoirs of the Indian Meteorological Department, vol. 24, Parts 9 and 10.)

problem is, however, too complex for a sufficiently complete theoretical solution to be possible at present, and the only method is the patient comparison of the pressure variations in each centre of action with the subsequent variations in all twenty centres. This laborious research has been carried out, and the results are presented in Part 9, "A Further Study of World Weather." The quarterly means are compared with those for two quarters before, one quarter before, the same quarter and one and two quarters after, at all stations—some 4000 correlation coefficients in all. From these coefficients 189 relationships are found which are probably significant according to the author's rigid standard, and are of value for seasonal forecasts either six months or three months ahead.

The consistency of the relationships is very remarkable, and "supports the view that seasonal forecasting is capable of wider application than at present." Most of the significant relationships discovered are between the different tropical and sub-tropical centres, at which weather abnormalities usually persist for several months, and the research indicates possibilities for the initiation or improvement of seasonal forecasting in such regions. For countries within the temperate storm belts, such as the British Isles, the outlook is not so hopeful; the significant correlation coefficients are fewer and smaller, and the fluctuations from month to month are often so great that the value of a general three-monthly forecast is limited. The final solution of the problem of long-range forecasting in temperate latitudes will undoubtedly have to take account of world-relationships, but only as giving a general tendency to the weather, the fluctuations of shorter period being determined by other and more local causes.

In Part 10 Sir Gilbert Walker returns to the original purpose of these studies and gives an example of the application of the results to seasonal forecasting in India. From the closest relationships found between rainfall in India and the preceding conditions in other parts of the world, greatly improved formulæ are deduced for forecasting the monsoon rainfall of different districts and the winter precipitation of the Himalayan region. The formulæ impress one very strongly with the meteorological unity of the world, that for Peninsula rain, for example, depending on the preceding conditions in such widely scattered regions as Alaska, South America, and Rhodesia. The statistical basis is sufficiently complete for the forecasts to be made confidently; and while in the story of Indian forecasting, begun fifty years ago, the final chapter is not yet written, we may reasonably believe that the main lines of the plot have been laid bare.

University and Educational Intelligence.

IN the course of an address delivered on September 4 at the opening of a new secondary school at Preston Lodge, East Lothian, Lord Balfour made some noteworthy remarks on the relation of schools to universities and on the importance of research in pure science. If the university is compelled to act the part either of the primary or secondary school its work is hampered, its utility diminished, and its wheels clogged. The purpose of the secondary school is, however, not merely to prepare students for the university, but rather to give an education by means of which those who are unable to go to the university can face life without feeling seriously handicapped. Referring to the importance of the practical teaching of science, Lord Balfour said he was glad to learn that science is to form a prominent part of the curriculum of the new school, and that it is to be taught by laboratory demonstration and experiments. "In-

dustry in the future," he said, "must be based upon science." If industrialists imagine that science can be built up without a disinterested love of knowledge, they fall "into the most grievous blunder." The multiplication of subjects in modern secondary and university education and the specialisation it entails are regarded by some as disastrous to the progress of education and the highest interests of culture and learning. Lord Balfour stated that, if the dangers of specialisation are kept in view, they can be reduced to a minimum, and the necessary flexibility, variety, and complexity of modern education successfully maintained.

THE Geographical Association has been experimenting for some time in the matter of conducted educational tours for teachers under the direction of volunteer experts. Some teachers and members of several universities joined a group of honours students in geography, of the University College of Wales, Aberystwyth, at Easter, in a tour around France, under the direction of Miss S. Harris, of the staff of that College. At the beginning of August, two groups left England to study the Alps, one the western Alps, starting from Chamonix, and one the eastern Alps, starting from Innsbruck. They were under the leadership, respectively, of Mr. J. I. Platt and Miss S. Harris, both of the University College of Wales, Aberystwyth. Among their objects was the demonstration of the newer views of earth history, and especially of mountain building, to which MM. Argand and Staub have given expression in the last few years. The charabanc has made it possible for teachers to intensify their knowledge of Britain, and tours have been organised to various natural regions of England, and to North and Central Wales, to demonstrate structural and general physical features with particular reference to the ways in which these factors have affected settlement, industries and communications. These tours were organised under the leadership of Messrs. E. E. Lupton and V. C. Spary. The Tours Committee of the Geographical Association would like to experiment further by specialising on selected regions for more intensive study if a sufficient number of members and intending members care to take part. All communications, concerning tours should be sent to the honorary secretary of the Tours Committee, Mr. E. E. Lupton, 73 Bierley Lane, Bradford.

THE Institute of Intellectual Co-operation, of which the governing body is the League of Nations Committee on Intellectual Co-operation, presided over by a French member of the Committee, is expected to open its doors towards the end of the year. The directorate of the Institute is composed of the following members: M. Bergson, M. de Reynold, Prof. Lorentz, Prof. Gilbert Murray, and Senator Ruffini. The Director is M. Julien Luchaire, Inspector-General of Education in France. The budget for 1926 amounts to 2,100,000 French francs, two millions of which represent the grant made by the French Government and 100,000 that of the Polish Government. The Committee at its meeting of July 27-30 approved of the adoption of an international students' card as recommended by the International Students' Federation. It took note of a memo by Dr. Hagberg Wright, Director of the London Library, on the subject of the international borrowing of books, and recommended a series of practical measures for facilitating such loans. It considered also questions relating to intellectual property, an international meteorological bureau, an international university for the training of statesmen, journalists and others, the unification of scientific nomenclature, and a loan for the development of intellectual life.

Early Science at Oxford.

September 16, 1684. Dr Plot began reading his discourse *de Origine Fontium*; half of which being read, we proceeded to other matters.

A letter from Dr Pit was read, which promises his discourse concerning Digestion; and gives an account of a woman, who, by reason of stoppages for three monthes, complained of a load, and fullness of her stomach; vomited blood, flesh, and blood-vessels, as big as goose quills, after which, by ye help of some Physick, she recovered.

A Letter from Mr Molyneux, dated Dublin September ye 2nd, 1684, was read: It gave an account, that Mr Osburn had observed ye last solar Eclipse near Tredagh in Ireland, lat: 53°. 40'. Initium H. 1.37' 30". finis H 3.56' 20".

Merchant Wayt's account of his peice of Incombustible Cloth was read

A Letter, written at ye Request of this Society, by Mr President, to be sent to ye head of each of the Universities in Scotland, for the establishing a Correspondence in that Kingdom, was read

Sir Robert Sibbald's *Scozia Illustrata*, was presented ye Society

Dr. Mark, an ingenious Brandenburg Gentleman, was proposed, in order to be elected a member of this Society

September 23, 1684. Dr. Plot continued ye reading of his discourse *de Origine Fontium*, and severall other things were offered to ye Society, but ye company being very small, they were referred to another meeting

September 30, 1684. Dr. Plot made an end of reading his Discourse *de Origine Fontium*, after which, ye Society gave him their thanks, for communicating to them so succinct an account, of what has been delivered by other writers, and of his own observations, on this subject; and also made it their request, that he would be pleased to print ye same.

A letter from Mr Aston, dated September ye 25th, was read; in it were contained some observations of ye late solar Eclipse taken by severall French astronomers, and printed in ye *Journal des sçavans*. They are translated into English, and will suddenly be printed in ye Transactions

Part of a Letter from Dr Cole of Worcester, dated September ye 27th, was read, which informed the Society, how very ready that learned physitian is to correspond with us, and to communicate to us, whatsoever shall occur to him fit to be imparted

Dr. Plot communicated an old silver ring, lately found in Staffordshire, with this motto, *in Godt al*; and an old Roman brass ring gilt about two ounces, 3 drams in weight, sent him by Mr. Packer, Physitian at Reading; this ring had a cornelian set in it, and four collets round ye cornelian, for as many stones more, three of which were lost.

A large stone, consisting of severall Branches, taken out of ye kidney of a woman by Mr Packer, was communicated by Mr Westead. An Account of this Stone will be printed in a little time.

Spongia arborescens erythraformis, i.e. of ye forme of Samphire, from Devonshire; and some of the button berries, from Jamaica; as also some Kelp, embroydered with ye shells of fish growing on ye leaves of that plant, (all which are a part of that present the generous Mr. Cole of Bristol lately made this University), were communicated to us by Dr. Plot.

Dr Caspar Marck having been proposed, Sept: 16th, his admission was now put to the Ballot, and carried in ye affirmative, after which he subscribed to the Articles.

Societies and Academies.

LONDON.

Institute of Metals (Autumn Meeting, Glasgow), September 3.—Robert J. Anderson and Everett G. Fahiman: The effect of low-temperature heating on the release of internal stress in brass tubes. The work was carried out to determine a suitable heat-treatment which would prevent warping of manufactures made of lead-brass tubing on standing for a period at the ordinary temperature, and at the same time effect stress release without material loss in hardness and strength. Heating for 2 or 3 hours at 325° C or for 4 hours at 300° C. in the case of material reduced 22 ½ per cent in area is satisfactory, but the mill control of separate lots of tubing must be substantially identical if a given heat-treatment procedure is to be applied to the material.—L. H. Callendar: Passivation and scale resistance in relation to the corrosion of aluminium alloys. Aluminium is a passive metal; its normal reactions are modified by the presence of a hydroxide scale of high mechanical, chemical, and electrical resistance. Corrosion in water may be started by solution or peptisation of this scale, it may be stopped by precipitation of scale on the metal surface. Chlorides reduce the resistance and adherence of these scales, and carbonates tend to increase scale resistance. Nitrates passify the metal by direct oxidation and anodic polarisation. Dichromates combine the passifying action of nitrates with the formation of a highly resistant scale containing chromate.—O. W. Ellis: The influence of pouring temperature and mould temperature on the properties of a lead-base antifriction alloy. Within the limits of the experiments, the replacement of lead by antimony increases the resistance to compression and increases the hardness. The replacement of tin by copper increases the resistance to compression but scarcely affects the hardness. Mould temperatures are more important than pouring temperatures. There is evidence of an intermetallic reaction in the copper-bearing alloy in the liquid state at 334° C.—R. H. Greaves and J. A. Jones: The effect of temperature on the behaviour of metals and alloys in the notched-bar impact test. Copper, aluminium, and lead showed a continuous fall in impact figure from -80° C. to the melting-point. Maxima in the impact figure-temperature curves were shown by tin at 0°, zinc at 150°, duralumin at 400°, lead-free 70:30 brass at 800°, 60:40 brass at 715°, 10 per cent aluminium bronze at about 750° C. On the other hand, 70:30 brass containing 0.02 per cent. or more of lead, and coinage bronze, showed no similar improvement in impact figure at high temperatures. A high notched-bar impact figure seems to indicate good rolling properties; for many alloys there is a range of temperature within which their behaviour on rolling is likely to be worse than at either higher or lower temperatures.—D. Hanson and Marie L. V. Gayler: On the constitution of alloys of aluminium, copper, and zinc.—Harry Hyman: The properties of some aluminium alloys. Aluminium alloys available for sand castings for engineering purposes generally possess low ductility, and this renders them difficult to manipulate in workshop practice; also they are readily susceptible to corrosion. A series of alloys was prepared with the view of passing a minimum test of 5 tons yield point, 10 tons breaking stress, and 5 per cent. elongation on sand-cast test-bars, and at the same time capable of undergoing a severe salt spray corrosion test without marked loss in weight. The alloy B.S.7, containing copper, nickel, iron, and magnesium, gave the most promising results, and has

been adopted on a commercial scale.—Douglas H. Ingall: The high temperature-tensile curve: (a) Effect of rate of heating; (b) Tensile curves of some brasses. For any given load the breaking temperature and the critical inflection temperature are lower the slower the rate of heating. In the lower temperature, straight-line portion of the curve, the relationship between breaking temperature and rate of heating may follow a hyperbolic curve, which would establish a definite fundamental tensile strength for any given temperature. Alloying increases the number of loops in the higher temperature curve over a given range of temperature, this is probably due to space lattice distortion. The high temperature-tensile curves of the brasses indicate that the solution of zinc in copper, over the α -range of composition, is not simple.—George B. Phillips: The primitive copper industry of America. There was a pre-historic copper industry in America, carried on by aborigines, who made widespread use of copper for tools, weapons, implements, ornaments, and ceremonial objects. This extensive manufacture of copper implements of similar shape to take the place of the stone and bone articles formerly used seems to justify the claim of a primitive copper culture for the American Indians, suddenly interrupted by the arrival of the Spaniards.—D. Stockdale: The α -phase boundary in the copper-tin system. Specimens were brought into equilibrium by quenching from a high temperature followed by long heat treatments at the supposed temperatures of the transformations. At ordinary temperatures the solubility of tin in copper is much higher than any previous diagram indicates; it is 16.0 per cent. of tin by weight. This result does not affect bronze-bearing metals, because such material when originally cast consists of the α and δ phases, and the hard δ shows no tendency to dissolve in the soft α at low temperatures. The existence of a transformation in the β phase has been confirmed.

Hovasse: The Ellobiopsidæ, propagated by flagellispores.—J. Dumas, G. Ramon, and Said Bilal: The immunising properties of dysenteric anatoxin.

SYDNEY.

Linnean Society of New South Wales, June 24.—J. R. Eyer and A. J. Turner: The Australian species of *Oncopera* (Hepialidæ, Lepidoptera). A key to

the species is given, based on the characters of the male genitalia, as well as a key to the superficial characters. Two species are described as new, making four species in all in the genus.—A. B. Walkom: Fossil plants from the Narrabeen stage of the Hawkesbury Series. Near the base of the stage, a few species have been found representing a survival of the *Glossopteris* flora. Higher up, the flora is quite distinct from the *Glossopteris* flora, and about twenty species are known. No description of this flora has been published hitherto.—A. Eland Shaw: New genera and species (mostly Australasian) of Blattidæ, with notes, and some remarks on Tepper's types. Notes are given on many of Tepper's types in the South Australian Museum. Four genera and twenty-five species are described as new, and an attempt has been made to explain some of the peculiarities of structure in the *Panesthinae* most strongly evidenced in the earth-digging group.

The Future of the British Patent Office.

IN the issue of NATURE for February 7 of the present year, we dwelt at some length upon the qualifications which were called for in the head of the British Patent Office, and concluded that the responsibilities of the Office were such that the staff should be presided over by a man eminent in science. The interest which our remarks aroused, combined with the passing of time when a new official in the ordinary course of events will be appointed, lead us again to refer to the same subject and to emphasise the importance of the position occupied by a Comptroller-General of Patents and the desirability for the post to be allotted to one in whom discoverers, inventors, scientific workers, manufacturers, and lawyers would have confidence.

As we have already pointed out in our former article, the duties of a Comptroller are multifarious. Apart from those in which science, industry, and law occupy so great a part, there are many duties referable to clerical management—which, very properly, may be assigned to a subordinate. With these duties, however, we are not here concerned. We desire rather to consider some special aspects which we trust will be present in the minds of those who in due course will be called upon to select the individual best fitted to perform the functions inherent in one of the important offices in the State.

Under the Patent Law Amendment Act of 1852, down to January 1884, the granting of patents was in the hands of the Commissioners of Patents, among whom were the Lord Chancellor and the Master of the Rolls. During that period, therefore, the department was almost entirely of a legal character and only remotely associated with the manufacturing classes. When the Patents Act of 1884 came into operation—now superseded by other Acts—the Patent Office was created and its functions transferred to the Board of Trade, in the control of which the Office has continued to the present day. At the same time, in 1884, a body of examiners was created, composed of persons who, by their training, were qualified in the various branches of industry and science in which they had had experience. By a further section of the Patents Act a Comptroller-General was appointed head of the Patent Office.

Since January 1884 three Comptrollers have successively held office. Without in any way attempting to depreciate the great abilities which have been shown by these Comptrollers in their respective spheres, we may say that none has held high position at the Bar, or has been in close touch with the manufacturing interests of the community, or has been distinguished in scientific circles. Each appears to have been content to be strictly "official." Some may perhaps see in this the truly distinctive British policy of "muddling

through," a policy which, however successful in the past, is not necessarily bound to serve in the future. But a policy such as this is by no means compulsory; on the want of a suitable candidate being known, there would be found many whose qualifications are of the highest who would be willing to undertake the responsibilities of the post, provided the remuneration offered was commensurate with the duties to be assumed and approached the salary obtainable outside the Civil Service.

It is only fair to remark, however, that the policy since 1883 has resulted in some substantial gain, and that a definite amount of progress has been secured. Thus mention has been made in previous articles of the setting up of a system of a limited search for "novelty" and a publication of abstracts of all specifications. Minor alterations in the law have also brought about the changes which the public has demanded, while the payment of fees, many of which are on a low scale, has been facilitated. But, speaking generally, the Board of Trade has been content to follow some distance behind public opinion and has resisted changes until agreement had been arrived at on all sides. One is almost tempted to say that the pouring into the national revenue of profits from the Patent Office of annual sums exceeding 70,000*l* has had a soporific effect upon the Board of Trade, with the result that stagnation rather than progress has resulted. Now, within a measurable distance of time, the Board will have to appoint a new chief of the Patent Office, and thereby to settle for a considerable period the silent but certain trend of affairs in a department where the interests of all classes of the community meet on a common level.

The same problem which is involved in the selection of the chief of the Patent Office has also presented itself to the Government of the United States of America. It would be well, therefore, to consider for a moment the way in which that problem has there been attacked. In the United States, as in Britain, administration of the Patent Office involves mixed questions of law, science, and technics; and it appears to be the present policy of the U.S. Office, in the first place, not to promote any examiner to the position of Primary Examiner unless he has studied law and become a member of the Bar, it being premised that an examiner before entering the Office has passed a severe examination in science and industry. The Commissioner of Patents is chosen from among the patent lawyers or, in some instances, by the promotion of Assistant Commissioners of Patents who have risen through all the grades in the Office. It is, however, generally understood that neither the Patent Bar nor the industrial interests would tolerate the appointment of a Commissioner who had had neither a scientific education nor extensive experience as a patent lawyer. Custom and public sentiment in the United

States demand that a Commissioner of Patents shall have had large experience in the practice of patent law and either a scientific education or extensive dealing with scientific questions.

Powerful advocacy for a thoroughly efficient Patent Office is to be found in the speech of the Prime Minister when reviewing the nation's position in the debate upon the unemployment question in June last. Mr. Stanley Baldwin said on that occasion that—

"No one will assert that British Industry can be saved by science alone, but it is none the less true that until scientific methods and scientific men can take their place in industry, and an equal place with the administrator and the financier, British trade will never be strong enough or resilient enough to meet the shocks that it is bound to meet as the years go by; to meet the sudden and unexpected changes which will always arise in international trade."

As the *Times* commentator expressed it: "Mr. Baldwin, as a business man himself, knows that there are thousands of people among us who already work up to the limit of their capacity and their strength. But he thinks that many employers by using their brains could add another ten per cent. to the efficiency of their several industries, and he touched briefly on some of the lines on which our conservative methods and practice might be improved."

It is an aim of the patent system to stimulate and assist employers in securing this increase of ten per cent. efficiency. The head of the Patent Office, with the qualifications which we have expressed, might be expected to make his influence felt not only within the narrow limits of his department but also in other regions far removed from bureaucratic control. The cry throughout the country is for increased production. To the discoverer and inventor we must look for a cutting adrift from old contrivances and for the best means and the most expeditious ways of bringing into being those necessities upon which our welfare as individuals and as a nation so much depends. Stimulation to industry and to invention is demanded if the position which the country held in the nineteenth century is to be recovered. A Comptroller-General high in scientific, engineering, and other technological societies, in touch with industrial concerns, and acquainted with the special needs of the various classes of persons to whom the industrial use of inventions is of paramount importance, would know best how to make the Patent Office play an effective part in the furtherance of the general advance.

We have set out in some detail the main qualifications which we think are desirable in a Comptroller of the Patent Office. That there are many in whom these qualifications may be found we have no doubt. There

are some even in the Civil Service who, not having surrendered themselves to the cramping conditions of their environment, could adequately fill the post. It is fairly certain, however, that a greater choice lies to hand outside the ranks of the Service; for, in general, it is more probable that the ideal man has already come to the front in situations where foresight, intelligence, and business capacity, unfettered by artificial restriction and official timidity, have been essential to success.

When such a man has been discovered, we may consider for the moment how his services are to be obtained. What are the inducements for him to leave his present position and to submit to the ruling of the permanent officials under whom the Patent Office is administered? At the end of a quiet and successful domestic career in the Civil Service there awaits the holder of an important position the companionship of an illustrious order with a possible knighthood. In extreme instances a Civil Servant becomes ennobled. In these respects, however, service under the Crown does not differ materially, or for the better, from commercial service. What then are the pecuniary advantages? Apart from security of tenure of office, which of course is a valuable asset, the salary attaching to the Comptrollership is altogether inadequate to attract the class of man who is so eminently desirable. The salary of the Comptroller of Patents is 1500*l.* per annum. To this there must be added a bonus calculated according to the published scale, say a sum of 200*l.*, which makes 1700*l.* in all. It may be said frankly and once for all that for such a sum the man who has given proofs of his ability in other walks of life to conduct the business of the Patent Office upon fitting lines is not to be found. The sum must be increased if the proper man is to be attracted to the post.

The Board of Trade, in conjunction with the Treasury, have the matter in their hands, for it is extremely unlikely that Parliament, which has the final control of salaries, would reject an increase which is shown to be necessary for securing the services of the right man. This selection is not merely a domestic matter which alone concerns officials in the Civil Service; it is one that affects industrialists, whether employers or employed. The issues are serious. Are we content to jog along as of old, making a minimum of progress even if stagnation is not present? Or are we to see assistance rendered in every department of industry, assistance in bringing forward the backward inventor, assistance towards the perfecting of the inventors' schemes and the securing of their best practical forms for immediate use by the public? It is therefore for the Board of Trade at the proper time to show that it is alive to the potentialities that await its selection of the head of the Patent Office.

The World's Scientific Periodicals.

A World List of Scientific Periodicals Published in the Years 1900-1921. Pp. xii+499. (London: Oxford University Press, 1925.) Two volumes, 3*l.* 10*s.* net (in cloth) or 3*l.* 3*s.* net (in paper).

THE "World List of Scientific Periodicals" had its origin in a letter written in 1920 by Sir Sidney F. Harmer, Director of the Natural History Departments of the British Museum, to Dr. P. Chalmers Mitchell. Sir Sidney Harmer asked that the Conjoint Board of Scientific Societies might consider the possibility of preparing a list of the chief scientific periodicals with an indication of the libraries in which these might be consulted. Dr. Chalmers Mitchell at once declared himself a warm advocate of the idea. Indeed, as secretary of the Zoological Society, and an enthusiastic supporter of the "Zoological Record," he had already taken some steps toward the inclusion in the "Record" of some indication of the libraries where the periodicals indexed could be found. Before the War, the Council of the Zoological Society had granted a small sum of money to compile a list of periodicals containing zoological articles, with indication of the libraries in London which had these periodicals on their shelves. This compilation had not been completed when war broke out.

The effort then made showed that the task of drawing up a list to show where each periodical could be consulted was a formidable one. While some periodicals are taken by several libraries, others are only to be found in one or two libraries, and many are not taken by any library in Great Britain. Even when a periodical is subscribed for, it is sometimes found that the series on the shelves is incomplete.

The Executive Committee of the Conjoint Board of Scientific Societies at once adopted Sir Sidney Harmer's suggestion in principle, provided that it should cover all branches of science. A Committee was appointed consisting of Sir Sidney Harmer, Mr. F. W. Clifford, Sir Richard Gregory, Dr. P. Chalmers Mitchell, Dr. A. W. Pollard, and Prof. W. W. Watts. The Committee decided that scientific periodicals in existence from January 1, 1900, should form the list, that the libraries to be indicated as taking in these periodicals should be those in London, Oxford, Cambridge, Edinburgh, Dublin, and Aberystwyth, and that, whenever possible, at least one library in the United Kingdom should be indicated for each title.

The objects of the list were declared to be:

- (1) To supply a list of current scientific periodicals as nearly as possible complete.
- (2) To indicate, where possible, at least one library where each periodical is taken.

(3) To form a basis for co-operation between libraries, so that both the number of duplicates and the list of periodicals not taken in at any centre may be reduced.

(4) To enable any library to use the list for its own purposes, by placing a mark against the title of each periodical it possesses, or by cutting up the pages to prepare a Card Catalogue. The list is accordingly printed only on one side of the paper, so as to make cutting up practical or to afford space for additions and annotations.

The Trustees of the British Museum not only recognised the importance of the enterprise as an aid to scientific research and as a means of increasing the usefulness of the libraries of Great Britain and Ireland, but also, on the recommendation of Dr. Pollard, then Keeper of Printed Books at the British Museum, supported by Sir Frederic Kenyon, Director and Principal Librarian of the Museum, they allowed the compilation of the list to be undertaken by the staff of the Museum as part of their official duties.

It soon became apparent that the magnitude of the work undertaken was such that the cost of preparation and publication could not be covered by subscriptions and sales. At this point, Sir Robert Hadfield and Mr. Robert Mond gave provisional guarantees to enable the work to proceed. The Trustees of the Carnegie United Kingdom Trust then guaranteed the sum of 1000*l.* towards the cost of production, on the condition that the number of centres with important libraries to be dealt with in the list should be greatly increased. This change in the original plan considerably increased the cost of preparation. Early in 1923 the Conjoint Board of Scientific Societies came to an end, but before its dissolution it entrusted "The World List" to Sir Arthur Schuster, Mr. Robert Mond, and Dr. P. Chalmers Mitchell, who undertook to form a company limited by guarantee to complete, own, and conduct the World List. Such a company was duly incorporated with a council of management consisting of Dr. P. Chalmers Mitchell (chairman), Sir Arthur Schuster, and Mr. Robert Mond. Miss Joan B. Procter became secretary. The original Committee was appointed as Advisory Committee, so that, except for the formal change in ownership and responsibility, there was no break in the control.

The actual compilation has been carried out, under the direction of Dr. A. W. Pollard, by Mr. W. A. Smith and Mr. L. A. Sheppard. Mr. Leonard Wharton has helped with the Slavonic entries. The periodicals catalogued are not only those in British libraries, but also all those concerning which information could be obtained from any part of the world.

Very special thanks are due to the Trustees of the British Museum and to the Keeper of Printed Books

for allowing this work to be done by members of the staff of the Museum. It should, however, be mentioned that Dr. Pollard points out that it is only in very exceptional circumstances that any library can undertake to catalogue books not contained within its walls. He therefore suggests that there is a real need for a small "flying squad" of trained cataloguers and bibliographers who would help to make the wealth of books in English libraries available for students.

The actual list now published contains the titles of 24,128 periodicals. This is really a remarkable figure, when it is remembered that the number of periodicals indexed by the International Catalogue of Scientific Literature is only about 9000. In arranging the titles inessential words are disregarded and words regarded as unnecessary are cut out. The care with which these abbreviations have been made is, on the whole, judicious, but it is surely a mistake to change plurals into singulars in all the large headings. The title of the *Comptes rendus* is given as "Compte rendu hebdomadaire des séances de l'Académie des sciences, Paris."

This change from plural to singular is made in order that the periodicals beginning *Compte rendu* may be classified together with those beginning *Comptes rendus*. There are no less than ninety journals beginning with these two words either in the singular or in the plural, and the compilers evidently disliked having one list of journals beginning *Compte rendu* followed by another list beginning *Comptes rendus*. The "World List of Scientific Periodicals" will for a long time be the standard work to which authors will refer when anxious to quote the exact title of a journal. In these circumstances it is desirable that the titles given should be quite accurate in the list, and that any difficulties in classification should be overcome by laying down some general rules such as "In fixing the alphabetical order of the titles indexed, the plural 's' is disregarded." This would be on a par with the plan adopted in Watts's "Dictionary of Chemistry," where the prefixes "bi-," "tri-," etc., are disregarded so that bicarbonates and carbonates may come together.

The volume now published contains a numbered list of scientific periodicals. The scope of the term "scientific" is that laid down in the International Catalogue of Scientific Literature. The present volume does not give indications of the libraries in which the periodicals may be found. A second volume, to be issued shortly, will contain a list of numbers corresponding to the numbers allotted to the titles in this volume, followed by a standard abbreviation of the title and reference letters indicating the libraries filing each periodical.

An exceedingly valuable addendum to the list is a catalogue of international congresses. It is most

necessary that scientific workers should know how to get access to the accounts of papers read and discussions held at these congresses and conferences. Hitherto, there has been nothing approaching a complete list of these publications, still less any indication as to where they can be consulted. Mr. Gomme, of the Patent Office Library, has given much personal attention to the preparation of this catalogue of proceedings at international congresses. All who are interested in the advance of scientific knowledge will be grateful to him for the care he has given to this section.

Our thanks are due to all those who have ungrudgingly given time and thought to the successful working out of this great undertaking, and to those who gave financial assistance when the project seemed likely to fail from lack of funds to carry it on. Dr. P. Chalmers Mitchell, who signs the preface, has evidently been the driving force ready at all times to meet and overcome difficulties as they arose. The task has been great, but those who undertook it have resolutely set themselves to accomplish it and have brought it to a successful issue.

Jungle-Folk of India.

The Birhors. a Little-known Jungle Tribe of Chota Nagpur. By Rai Bahadur Sarat Chandra Roy. Pp. viii+608+36 plates. (Ranchi: *Man in India* Office, 1925.) 10 rupees; 15s

THE Birhors dwell in the jungles which fringe the eastern margin of the great central 2000 ft plateau of Chota Nagpur, in the Province of Bihar and Orissa. Like so many other primitive communities, they seem doomed to perish under the impact of modern life; between 1911 and 1921 their number fell by more than 30 per cent (from 2340 to 1510). Mr Roy's monograph is a timely record of a dying race.

Some of the Birhors are "settled," and eke out a livelihood by burning patches of jungle and raising a scanty crop of maize and beans. But their normal mode of life, to which even settled Birhors often revert, is nomadic; the fauna and flora of the jungle supply them with food and with the *chōp* fibre (*Bauhinia scandens*) which they make into rope and barter for such clothing, condiments, etc., as they cannot produce themselves. The Birhors eat almost anything; whether they ever ate their ancestors, as commonly alleged, is an open question; the case against them is not yet proved.

Racially the Birhors resemble the more virile Mundas and Oraons of Chota Nagpur. Their language is a dialect of that Austric family which straggles round half

the globe, from Madagascar to Easter Island. Their social organisation, as elsewhere in India, is based on clan exogamy, but in the economy of daily life the kin-group yields precedence to the clan-group, or *tāndā*, a word applied also to the encampments of Lambadi (Banjari) gipsies who were once the carriers of peninsular India and the Punjab. The *tāndā* consists of from 3 to 10 families, belonging to various clans, associated together for subsistence. Each *tāndā* has its captain (*nāyā*), its magician (*māti*), and its messenger (*diguār*), its own spirits (*sāngi bhūt*), and its own hunting expeditions. Mr. Roy explains in detail their hunting ritual and the partition of the spoil. Once a year several *tāndās* unite in a "regional hunt"; otherwise inter-*tāndā* relations are limited to wedding festivities and adjudication on infractions of tribal law.

The clan system, as usual, regulates matrimony. Mr. Roy names thirty-seven clans, and the list is not exhaustive. Most of the clan names are "totemistic," but some connote localities and some clans bear the names of alien castes and tribes, which indicate some infusion of alien blood. Each clan has its peculiar traditions, observances, and cults, and several clans are admittedly of hybrid origin. Broken folk cannot afford to be exclusive.

Lads and lasses are schooled by the familiar "dormitory" discipline of primitive culture. The dormitories are not exactly shrines of purity—boys will be boys,—but schoolboy etiquette insists that a lad should stick to his own sweetheart and not poach. With marriage comes respectability. Of marriage there are ten forms, nine of them informal and gallant, the tenth only is "regular," heavily laden with the elaborate negotiation and formalism in which India delights.

Mr. Roy's appraisal of Birhor religion is kindly and sound. He rightly discriminates between "personal" gods and spirits propitiated with prayers and sacrifices, and impersonal "powers, forces, or energies" controlled by spell or threat or other "magical" device. Religion to the Birhor is not all gloom and terror. Singbōngā, the supreme being, is benign enough, but, like other superior personalities, somewhat aloof. Then there are hosts of clan spirits, *tāndā*-spirits, family spirits (mostly ancestral), tutelary spirits, etc., whose censorship of moral lapses must exercise a salutary influence on social life. Mr. Roy's outline is clear and concise, and he neatly sums up the *summum bonum* of Birhor existence: "the power to control and direct the *impersonal* energies and powers and the stray *personal* powers—and secure the goodwill of the more important *personalised* powers or spirits."

In Birhor belief a man has two souls, one male, one female. When he dreams, the male soul quits the body, the female soul remains in charge, and the body

sleeps. But if the male soul lingers, its mate goes out to search for it, and the body dies; temporarily, perhaps, for the spirit-doctor (*māti*) is requisitioned and does what he can to call back the truant souls and restore life.

The Birhors are by no means untouched by Hindu influences, markedly so in the few religious festivals celebrated by certain clans, and in folk-tales of which Mr. Roy gives numerous examples. The Birhor version of the Rāmāyana is of special interest.

Students of Indian anthropology are deeply indebted to Mr. Roy for the light he has thrown on the past and present culture of the Chota Nagpur plateau. In the Bihar and Orissa Research Society's Journal he has opened up new ground in the archæology of his area. His monographs on the Mundas and Oraons are classics. "The Birhors" is yet another first-rate study, a study not merely of an obscure tribe but also of the workings of that mysterious complex of thought and feeling which go to make up human culture. The volume is handy in size and easily read, in spite of the numerous misprints inseparable from Indian typography. The plates are well chosen, but not too well printed. Mr. Roy is never a theoriser or a partisan; his ciction is simple and precise, his inspiration comes straight from the hearts of the humble folk he has made his friends.

F. J. RICHARDS.

Research at High Temperatures.

Fours électriques et chimie. Publié sous la direction de Prof. P. Lebeau, avec la collaboration de C. Bedel, Prof. A. Damiens, P. Fleury, Prof. P. Jolibois, Dr. M. Picon, Prof. G. Ribaud, Dr. H. Weiss. (Fondation Edmond de Rothschild pour le développement de la recherche scientifique.) Pp. xii + 585. (Paris: Les Presses universitaires de France, 1924.) n.p.

THE Committee of the Fondation Edmond de Rothschild has caused this book to be written as a preliminary step in the planning of investigations with electric furnaces, to extend scientific knowledge and industrial applications. It forms a review of electric furnace constructions and their applications and succeeds in covering the ground fairly thoroughly. Recognising that advances in chemistry and physics are frequently closely associated with the invention or development of new apparatus, an attempt is made to describe various types of electric furnace and to associate with the several forms a summary of the main researches already carried out by their aid.

Such a compilation has both its advantages and its dangers. Bibliographical surveys, or *documentation* as the French so aptly describe them, undoubtedly save

the investigator a lot of tedious work; and literary searching is not only wasteful of the time, but actually detrimental to the originality of the more able scientific worker.

On the other hand, there is a real risk that too much attention will be paid to the acquisition of replicas of the apparatus of the earlier workers, without due regard to the more important part which the inspiration and skill of these investigators played in its design and use. The history of the scientific application of electric furnaces itself provides an excellent example of the power of the able experimenter to override all limitations in apparatus and equipment. The late Henri Moissan is even to-day unsurpassed in the richness of his discoveries in this field, and yet he had, for almost the whole period during which he was engaged in these researches, only the most simple equipment, and the only supply of electric current in his laboratory was that which he could provide from primary batteries, the electric furnace work being carefully prepared beforehand but executed on occasional pilgrimages to a central supply station, several miles away from the laboratory.

Whereas the work of Moissan was concerned chiefly with the primary survey of the subject and the production of metals and new compounds, hitherto outside the practical scope of ordinary methods of heating, later applications have called for apparatus of greater precision. The need for close control of the working temperatures, as in the determination of such physical constants as the boiling points of the metals, for heating *in vacuo* to prevent the oxidation or the carburisation of metals; or for high pressure to attain measurable yields of some of the products of high temperature chemical reactions, has in each case led to the design of much more complicated apparatus. The description of this apparatus is fully dealt with in this book in seven chapters devoted respectively to electric furnaces of the following types: (1) metallic resistance, (2) carbon resistance, (3) vacuum, (4) high pressure, (5) induction and high frequency, (6) arc, (7) spark and gas discharge; whilst an eighth chapter summarises the methods of pyrometry.

With a subject that covers such a wide borderland of physics, chemistry, and electrical engineering, it is not surprising for a reviewer to be able to find a few omissions—such as all mention of the electric furnace production of silica glass—but the survey on the whole is remarkably complete and superior to what is generally provided by French scientific books; and it can be strongly recommended to English workers who have need of a reference book on the subject. The Fondation Edmond de Rothschild (see NATURE, 1921, vol. 107, p. 563) is one of the largest French endowments for

physico-chemical research, and the further development of this branch of its activities, which will apparently consist in supporting work to supplement existing knowledge in this field, will be awaited with much interest.

R. S. H.

Lakes.

Les lacs, leur mode de formation, leurs eaux, leur destin : éléments d'hydro-géologie. Par Léon W. Collet. Pp. xii + 320 + 28 planches (Paris : Gaston Doin, 1925.) 35 francs.

THE limnologist is fortunate in having at his disposal two such excellent works of recent date as Prof. Halbfass's "Grundzüge einer vergleichenden Seenkunde" and Prof. Collet's "Les lacs." Though the subject is the same, there is room for both. The mode of treatment is very different and there is little overlapping between the two. Prof. Halbfass's book is the more general. Prof. Collet's deals chiefly, though by no means solely, with the lakes of Switzerland and the Alps, and some of these it describes in considerable detail. Prof. Collet was formerly Director of the Swiss Hydrographical Service, and the accounts that he gives of the observations made by himself or under his direction form a valuable feature of his book. He also took part in Sir John Murray's survey of the Scottish lochs.

Prof. Collet's book is divided into three sections: the formation of lake-basins, the water of lakes, and the destiny of lakes. Under the last heading he includes not only the filling of lakes by deposition but also the utilisation of their waters. The first section occupies about a hundred pages. Owing to the somewhat sceptical attitude adopted by some writers in England, the English geologist will probably be most interested in the lakes attributed to glacial erosion and to solution. Prof. Collet himself has no doubt about the erosive powers of glaciers, and like Penck and Brückner believes that most of the lakes of the Alpine borders are due to overdeepening where the glaciers debouched upon the plains. Lake Geneva, however, has had a more complex history, which has not yet been fully worked out; and only the upper basin is due to this cause. In connexion with this question of overdeepening he gives an interesting photograph of the left bank of Lake Ritom. It shows glacial striations rising steeply from the water, the direction of the rise being towards the outlet. It proves, he thinks, and it certainly suggests, that the glacier itself rose towards the barrier at the lower end of the lake. Perhaps, however, even this will not convince the confirmed sceptic, for it is still possible that the greater part of the ice in the lake-hollow may have been stagnant and only the upper layers moving.

No geologist denies the efficiency of water as a solvent agent; and in Cheshire, depressions of the surface due to the solution, natural or artificial, of the salt beneath, are too common to leave any doubt as to their cause. But it is not so clear in England that any lake-basins have been formed by direct solution of the rock that occupied the hollow. Hollows have been produced in this way in our limestone districts, but they do not usually hold water, for there is generally an underground escape. In the Karst, however, and in the Limestone Alps, the conditions are more favourable, and Prof. Collet describes several examples. In some there is no visible outlet, in others a part of the water escapes superficially and a part underground. By means of experiments with fluorescin, Prof. Collet has shown that in several cases the subterranean outflow is not in the direction that the surface topography would lead us to expect.

The section on the water of lakes occupies 85 pages and deals with the influence of the regime of the affluents, the temperature, the chemical composition, and the colour. One of the most interesting parts of this section is the account of Lake Ritom. For stable equilibrium the water must increase in density downwards. Consequently in temperate regions, when there is no disturbance due to wind or other causes, the temperature of the water in summer decreases downwards; in winter, if the surface water is below 4° C, the temperature increases downwards. Lake Ritom sometimes shows a layer of cold water lying between warmer water above and below. The condition is due to differences of salinity. The upper twelve and a half metres—the measurements were made before the level of the lake was artificially altered—consists of oxygenated water with a low percentage of salts. From thirteen metres downwards the water is highly saline and contains sulphuretted hydrogen. There is a transition layer of about half a metre in thickness. The lower water is almost stagnant and has a temperature of about 6° C., varying little with the depth or with the season. The fresher water is never so cold as to become heavier than the salt water beneath, and consequently the convection currents in the former do not extend into the latter. The upper layer, in fact, behaves as if the salt water formed the floor of the lake and the temperature at this false floor is often less than 6° C.

The salts in the lower water are derived from the dolomitic and gypsum-bearing Triassic rocks of the region, not by direct solution of the walls of the hollow but from underground sources. Since the water is nearly stagnant the supply is doubtless very slow—it must, in fact, be so slow that it is balanced by diffusion into the upper layer. This upper layer consists of the

water from the visible affluents of the lake, which are all only slightly mineralised, and the fresher water flows over the saline layer and escapes by the river Foos.

The third section, consisting of rather more than a hundred and twenty pages, is the most important from the practical point of view, and should be consulted by engineers who have to do with the construction of reservoirs for any purpose. All lakes tend to be filled up in time by the deposits brought into them by streams and rivers, and the same is true of reservoirs. In a country like Switzerland the process is often much more rapid than in England. The original artificial lake of Perolles was filled in fourteen years, and the rate of deposition in other cases is equally high. This is one of the matters investigated by the Hydrographic Survey, and though the rate must vary greatly in different cases, the figures which Prof. Collet gives are of great value. They are, in fact, almost the only figures available which are more than guesses.

Sufficient has been said to show the interest of the volume. Prof. Collet writes very clearly and the book is admirably produced and illustrated. There are 63 maps and diagrams and 28 plates of photographs. Apparently the paper on which the text is printed is heavily loaded, for though the book is not bulky it is inconveniently heavy. This is the only fault that can be found with it.

P. L.

Our Bookshelf.

The Social and Political Systems of Central Polynesia.

By Robert W. Williamson. Vol. 1. Pp. xxix + 438 + 6 maps. Vol. 2. Pp. v + 496. Vol. 3. Pp. v + 487. (Cambridge: At the University Press, 1924.) 75s. net.

THE amount of labour involved in the writing of this book has been, literally, enormous. The bibliography of books covers eleven closely printed pages, and to these must be added innumerable articles in the scientific journals of which the titles alone occupy nearly a page. Yet the Sandwich Islands and New Zealand are not included, and except for an opening chapter on origin and migrations, no subject outside what is strictly social or political is discussed. Even such matters as the functions of the chiefs in relation to ritual observances are postponed, with other topics connected with religious ceremonies and customs, for future consideration in another work.

Within the limits that Mr. Williamson has set himself, his treatment has been thorough. The difficulties arising out of the often unsatisfactory, and sometimes contradictory, character of the evidence—evidence collected at widely separated periods of time, by individuals of very different powers of observation and of varying capacity for precision of statement—have been squarely faced and usually resolved into a coherent account. Mr. Williamson's examination of local and social grouping may be taken as a very fair sample both of the difficulties and of the results of his meticulously careful method of analysis. Limitations of space forbid

any critical examination of conclusions which are based upon a mass of detail drawn from so extensive a field; but it may be mentioned that Mr. Williamson finds that the fundamental factor in the social and political system of Polynesia was the recognition of the office of the head of the group, taking this term as applicable to functions ranging from those of the chief of the most extensive area under one authority to the head of a family group. Mr. Williamson is to be congratulated on the successful accomplishment of a heavy task by which he has earned the gratitude of all students of ethnology.

Automotive Electricity: a Text and Reference Work on the Construction, Operation, Characteristics and Maintenance of Automotive Ignition, Starting, Lighting and Storage Battery Equipment By Earl L. Consoliver. Pp. xv + 665. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925) 20s. net.

ELECTRICITY plays a most important part in the equipment of a modern motor-car. In addition to igniting the fuel charges within the engine cylinders, it starts the engine and illuminates the road for night driving. It also operates the horn and other signal devices, and in many cases it operates electric gear shifts, hand-warmers, cigar-lighters, and carburettor heating devices. It plays an equally important part in connexion with motor-boats and aeroplanes. There is a demand, therefore, for a book which will give a clear and trustworthy account of the ignition requirements, the starting and generating equipment, and the management of storage batteries.

The volume under notice, whilst disclaiming to be an encyclopædia, does touch pretty thoroughly on all these subjects. Naturally American practice is most fully considered, but most of the advice given is directly applicable to all makes of car. The title led us to expect that vehicles driven exclusively by batteries would be described and that their limitations would be considered. This branch of the subject, although an important one—more especially in the United States—is not considered. Many useful hints can be picked up from this book. The author has had considerable experience in instructing those who have to look after motor-cars; he gives the minimum of theory and lays stress on those points which are important in practical running.

Practical Advice to Inventors and Patentees: Inventions and How to Patent Them. By C. M. Linley. Pp. vi + 126. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 3s. 6d. net.

THIS thoroughly practical little book can be strongly recommended to inventors who wish to know how to exploit their ingenuity commercially, for its author appears to have learned the ropes in the hard school of experience. The principles of patent law and practice are set forth clearly in non-technical language and the exposition of these is sound, although the following points might be noted for future editions: a British patent cannot be invalidated by publication in a prior British specification more than fifty years old (pp. 47, 48), while it can be invalidated by publication in a foreign specification taken by the Patent Office library, whether or not there has been additional publication

in a periodical (p. 45); and p. 44 would be improved by the addition of a paragraph on the gentle art of phrasing disclaimers.

It is, however, when he comes to more practical topics that the author is at his best: he shows a keen insight into human nature and much ripe wisdom when he explains how to attract a capitalist, how to deal with infringers, how to combine discipline with fair play when inferior workmen become inventive, and how to perform a good many other difficult but profitable feats which are not mentioned in text-books of patent law. His anecdotes relating to the history of inventions also make good reading. The book is written in a conversational style and is all the more readable on that account, but it would be the better for a thorough revision of its syntax, which is in places slipshod.

Methods in Plant Histology. By Prof. Charles J. Chamberlain. Fourth revised edition. Pp. xi+349. (Chicago: University of Chicago Press; London: Cambridge University Press, 1924) 3 25 dollars.

SINCE the first edition of this book appeared in 1901 it has become a well-known manual of laboratory methods. Its usefulness may be judged from the succession of editions of continually increasing size. The present edition is largely re-written—a task necessitated in part by the stimulus to improvement in technique resulting from previous editions. There are additional hints on details of method throughout the book, and these are especially valuable in the field of cytological technique, where success—like genius—depends upon an infinite capacity for taking pains.

The Venetian turpentine method for mounting algæ has been made more specific and could doubtless be more widely used with advantage, as the staining results are brilliant when good preparations are obtained. A short chapter is added on the cellulose acetate method of softening woods for sectioning—a method developed by Dr. Kernot and Mrs. Williamson, which softens the hardest woods without destroying details of structure.

The standardisation of American stains, on which a scientific commission has been at work since the War, has led to a great improvement in dyes, which now often surpass the old Grüber stains, and incidentally has led to alterations in the directions for staining given in this book. Among the micro-chemical tests we are surprised to find no mention of aniline hydrochloride, which is such a useful laboratory reagent for lignified tissues.

R. R. G.

An Outline of Automatic Telephony. By William Aitken. Pp. 143. (London: Ernest Benn, Ltd., 1925.) 5s. net.

SINCE the introduction of automatic working, telephony is becoming more and more a highly specialised science. To the outsider the problem appears to be one of the greatest complexity. Any telephone in an area has to be connected in a few seconds with any other telephone in that area so that two persons can converse clearly and uninterruptedly for a given period. As a mistake in dialling is always possible, the caller must be able to break down the connexion at any instant. The cables between any two switching stages may be in use or faults may develop in them. Signals therefore have to be given to the caller to indicate abnormal conditions.

Further, supervisory signals have to be sent to the attendants and the sensitive pieces of apparatus have to be protected by suitable devices. Service has sometimes to be free, but generally it is either metered or obtained by "coin in the slot." As all these variations have to be done automatically and with the minimum risk of error, the difficulties that arise are unending, and telephone engineers are to be congratulated on having developed working systems. Mr. Aitken gives a good technical description of the various types of systems in use, particular stress being laid on the Strowger Director System, which is the one being installed in London. The system he adopts of describing the "circuits" is original and easily intelligible.

Sulphuric Acid Concentration. By P. Parrish and F. C. Snelling. (Chemical Engineering Library, Second Series.) Vol. 1: By Hot Gases. Pp. 141. Vol. 2: In Heated Vessels. Pp. 147. (London: Ernest Benn, Ltd., 1924.) 6s net each.

THE chief merit of these two small volumes is that they are written by practical men who possess a ripe and successful experience of sulphuric acid manufacture. For this reason they will be read and studied with profit by the works' chemist and engineer, whilst the fact that they contain a considerable amount of information which is not found in ordinary text-books will make them appeal to the teacher and student in technical institutions. From the educational point of view, however, they have one drawback, namely, defective composition: there is scarcely a statement in them which could not be put into clearer and terser English; but even this could be turned to good purpose by a capable teacher.

The accounts of the Kessler and Gaillard methods of concentration in the first volume, and of cascade systems in the second, are particularly useful, and, like the rest of the subject-matter, quite up-to-date from the point of view of British practice. Two chapters are devoted to constructional materials, and one to transport and storage. In the final chapter on possible developments, the view is expressed that in the future "chamber" acid (70-80 per cent.) and oleum will be produced simultaneously in one plant, and rectified acid (96-98 per cent.) will be obtained by mixing them on the spot.

The Wandering Scholar. By David G. Hogarth. Pp. v+274. (London: Oxford University Press, 1925.) 8s. 6d. net.

THIS book is neither a reissue nor a new edition, but in part is both. It is a combination of two books, "The Wandering Scholar" and "The Accidents of an Antiquary's Life," one published in 1896 and the other in 1910. Of the first, two chapters and some paragraphs are omitted; of the second, the introductory chapter. The account of the Anatolian Turk under the old Hamedian regime, a piece of description and psychological analysis of remarkable penetration and insight, is retained. Those, if any, who are unacquainted with these delightful sketches of travel and archæological exploration in Asia Minor, Greece, and Egypt, with their humour and their sympathetic appreciation of the people of each country, will be grateful for their reissue in the convenient form of a single volume.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Isotopic Composition and the Atomic Weight of Chlorine in Meteorites.

THE most accurate determinations of the atomic weight of chlorine indicate that on earth this element consists of 76 6₅ per cent. of chlorine of isotopic number 1 (atomic weight = 35) and of 23 3₅ per cent. of isotopic number 3 (atomic weight = 37). It is of interest to determine the composition of this element in meteorites, and this has been done by the present writers, with the result that meteoritic chlorine has been found to have exactly the above isotopic composition. Within the limits of error of extremely accurate work, the atomic weight of meteoritic chlorine is found to be the same as that of this element as found on earth.

Presumably the material of meteorites has not been mixed with that on earth within the last few billion years. Thus, if during this period there has been any disintegration or formation of atoms of chlorine, it has either (1) not affected at all the relative amounts of the two isotopes, or (2) the relative amounts have been affected to exactly the same extent in both locations. The additional possibility that the coincidence is accidental seems to be ruled out by the similar results of Baxter for the atomic weight of meteoritic nickel. Have the materials involved ever been mixed with sufficient thoroughness to explain these results? According to Harkins (J. Am. Chem. Soc., 39, 856 (1917); *Phil. Mag.*, 42, 332 (1921)) the atoms of the lighter isotope are more stable, and a large part, if not all, of the exhibited constancy of isotopic composition of elements is due to the net effect of the different types of atomic stability.

The average of the best results for the atomic weight of terrestrial chlorine is 35.467. The five results obtained by us on highly purified meteoritic chlorine are 35.466, 35.468, 35.469, 35.469, 35.465, with an average of 35.4674. The method used for the determination of the atomic weight consisted in weighing about two grams of extremely pure silver in a quartz flask, dissolving in nitric acid, and in finally adding hydrogen chloride obtained from a meteorite in sufficient excess to convert the silver completely to silver chloride. The water and acids were evaporated and the silver chloride fused, the last fusion being carried out in an atmosphere of chlorine. The balance used gave a deflexion of half a millimetre on the scale for a hundredth of a milligram. The methods used throughout were similar to those used by Richards and his associates, with the exception that the smaller amount of material available made it essential to use a balance of the highest sensitivity compatible with the requisite stability and constancy.

Chlorine from wernerite, from apatite, and from purified commercial hydrochloric acid gave results which were identical with those on the meteorite, within the limits of error of the work.

In calculating the percentages of the isotopes as given in the first paragraph, use was made of the Whole Number Rule of Harkins and Wilson (J. Am. Chem. Soc., 37, 1367-1421 (1915)) and the assumption was made that the atomic weights of the separate isotopes are exactly whole numbers. While any

deviations from these whole numbers affect the percentages given, it is obvious that they do not affect the identity of composition of meteoritic and terrestrial chlorine as exhibited by the identity in the atomic weights of the mixtures from the two sources.

August 11.

Coastal Errors in Radio Direction-Finding.

FOR many years now it has been the experience of those dealing with wireless direction-finders that when the path of the waves being received lies approximately parallel to the coast, an error in apparent bearing is obtained which may or may not be constant. It is probably correct to state that the error is always such as to indicate that the waves in crossing from sea to land experience a deviation in a direction towards the normal to the coast-line at a point of transit. This is consistent with the generally accepted assumption that the velocity of waves over sea-water is greater than the velocity over land, due to the lower conductivity of the latter. The magnitude of the possible error which may occur appears to be usually of the order of 3° to 5°, although greater errors up to about 10° are apparently sometimes experienced.

While a fixed transmitting station should, in the absence of night variations, give a constant bearing even including any coastal refraction effects, a little consideration of the case will show that several stations at different distances on the same great circle from the D.F. stations will give different errors. It is thus evidently impracticable to apply a correction to the observed bearing of a ship at a D.F. station without assuming a knowledge of its true bearing and distance, and it is becoming the practice of those in charge of shore D.F. stations to supply information as to the arcs over which the bearings supplied may be considered to be reliable.

In the experimental direction-finding work conducted by me during the last four years, errors have been measured in certain cases which appear to support the above experience. At one D.F. station situated on the east coast of England, the only cases in which consistent errors of more than 1.3° were obtained in daylight, were found to be those for which the direction of transmission was within 20° of the coast-line. On the wave-lengths of 450 and 600 metres employed in the majority of these particular observations, this coastal error was of the order of 3° to 4.3° for some of the transmissions. In one instance, in which the wave-length was systematically increased from 500 to 2600 metres, the corresponding error decreased from 3.2° to 1.4°. On higher wave-lengths the possible coastal error observed in this and all other cases was less than 1°. In every instance the error was such as to indicate a bending of the waves towards the normal to the coast-line, in passing from the sea to the land side of the boundary.

From Zenneck's analysis (J. A. Zenneck, *Ann. der Phys.*, 1907, vol. 23, pp. 846-866) of the case of a plane wave travelling over the plane boundary of a semi-conducting ground and non-conducting air, it can be shown that the velocity of wireless waves in a horizontal direction is greater over land than over sea. Hence the effective refractive index, which is the ratio $\frac{\text{velocity over sea}}{\text{velocity over land}}$, is less than unity, and a wave will be bent away from the normal in crossing

a coast-line from sea to land. Eckersley (T. L. Eckersley, *Radio Review*, 1920, vol. 1, pp. 421-428) has previously made a study of the refractive effects for wireless waves crossing the Egyptian coast from the Mediterranean Sea, and obtained experimentally a refractive index of 1.02 for a wave-length of 1000 metres. A theoretical value of 1.067 was given as being applicable to this case, but in view of the above remarks a mistake would appear to have entered into the derivation of this value.

It has been shown from recent measurements (R. L. Smith-Rose and R. H. Barfield, *Proc. Roy. Soc.*, 1925, vol. 107, pp. 587-601) that the effective conductivity of the ground in the south of England at wireless frequencies is approximately 10^8 e.s.u. If this value be used to calculate the refractive index for the English coast, taking the wave-length of 450 metres, the value of μ obtained is 0.999991. This means that the ratio of the velocities of these waves over the sea and land differs from unity by less than 10^{-5} , and it is thus difficult to account for the deviations which have actually been observed, quite apart from the fact that they are in the wrong sense. It must be remembered, however, that in such a case the deviation $\delta\phi$ of a wave crossing the boundary at an angle of incidence θ can be shown to be

$$\delta\phi = \frac{\mu - 1}{\mu} \tan \theta.$$

Hence, although $\mu - 1$ is only 10^{-5} for the case considered above, $\tan \theta$ tends to become infinite as θ approaches 90° . So that in the case of waves which pass along the coast at practically grazing incidence for a distance of several miles, the error may reach a value of two or three degrees as actually observed. Two difficulties in making a strict comparison with experimental results are that the coast-line is not usually straight for any appreciable distance, and that it is doubtful in many cases if the effective boundary between the sea and land is defined by the high-water mark used on charts. For these reasons the angle of incidence of the waves on the coast-line is a rather uncertain quantity. The problem is further complicated by the fact that the boundary is

measured. Since the land D.F. stations are often situated within a wave-length of the boundary, it is important to know exactly what is happening at such a short distance. Providing the change from one medium to another at the boundary is reasonably sudden, there appears to be no reason for supposing that the deviations of waves crossing it is not equally

FIG. 2.—Ripple photograph. Source S and observing station O on opposite sides of boundary. The wave front observed at O is not at right angles to the true bearing of S.

sudden. This point has been very nicely demonstrated by the analogous case of water ripples in which the change in velocity is produced by an alteration in the depth of the water in the ripple tank. The photograph reproduced in Fig. 2 shows that the change in direction is quite sudden and is complete within a fraction of a wave-length. Should the change in conditions from one medium to another be gradual, the resulting refraction should be gradual, and at the limit should be continuous.

Sex-determination in *Trialeurodes vaporariorum*.

THE common Greenhouse White Fly (*Trialeurodes vaporariorum*) presents a rather curious case of sex-determination. Originally (1903) Morrill in America discovered that it was parthenogenetic and that all unfertilised eggs developed into males; this finding was corroborated later on by Stoll and Shull (1919). Hargreaves (1914) and Williams (1917), investigating the same species in England, found, however, that in this country unfertilised eggs laid by virgin females exclusively gave rise to females. Random collections in America had shown a considerable proportion of males (40-50 per cent.), while in England, none or a few males were found; only one small colony found by Williams at Merton agreed with the American strain with regard to its sex-proportion.

These investigations indicate that *Trialeurodes vaporariorum* has two races, an "American," showing arrhenotokous parthenogenesis, and an "English" with thelytokous parthenogenesis, a most interesting fact, which, however, does not seem to be completely unique in the animal kingdom (cf. *Trichogramma pretiosa*, a Chalcid, Howard and Fiske, 1911). As to the progeny of mated females, Williams in the exceptional Merton colony had obtained both sexes after pairing of the mother individual, and therefore thought himself justified in concluding that fertilised eggs may give rise to both males and females. Stoll and Shull with individuals of the "American" race arrived at the same experimental result, but maintained that the interpretation might be the same as in the honey-bee, where the queen after mating can lay both fertilised and unfertilised eggs, developing into females and males respectively. Furthermore, it seemed probable that this is really the case, for they obtained in some experiments a great majority of females after mating, while if Williams's interpretation is correct, no more than 50 per cent. of the progeny could have been published.

generations. Attempts at crossing females of the "English" race with males of the "American" gave in all experiments together: in F_1 , 766 females + 1 male; in F_2 (parthenogenetic progeny of F_1), 999 females and 4 males. (Probably the males, which only appeared in 2 lines of 11, have originated from slight contamination of the initial material with "American" females.) Then even after the "crossing" the female-producing strain persists, i.e. probably no effective crossing has taken place. It is very likely, though hitherto not proved, that the rare males in the thelytokous strain do not differ genetically from the males of the arrhenotokous race. Therefore, instead of speaking about two races, one might just as well say that *T. vaporariorum* has two kinds of females: obligatorily parthenogenetic thelytokous and facultatively parthenogenetic arrhenotokous together with haploid males.

The cytological examination of the thelytokous females shows that the oogenesis up to a certain point goes on in just the same way as in the arrhenotokous ones. The chromosome number is the same; the usual leptotene and pachytene stages are met with in the prophase; a pseudo-reduction takes place, thus only 11 chromosomes are seen during the maturation divisions; two polar nuclei are produced: in short, the egg behaves just as if it was preparing for fertilisation or development with the haploid chromosome number. But afterwards the 11 chromosomes divide, and in all segmentation nuclei and later on in the larval mitoses 22 chromosomes always are found. So close a resemblance in the behaviour of the chromosomes within the same species between obligatorily parthenogenetic eggs and eggs that can be fertilised has been found in scarcely any other animal.

For further particulars and discussion I must refer to my detailed paper which will probably be published in the course of the winter. In the same paper will appear an examination of the cytology of *Aleurodes proletella*, in which species I have been able to prove that really only one maturation division takes place in the oogenesis of the haploid males, while in the thelytokous females the parthenogenesis

University since the second half of the 16th century this passed through a period of great splendour in the early 19th century, shortly after the partitions of Poland, and it has been revived now; Leopold (which the Germans call Lemberg, and the Poles Lwow) celebrated its 250th anniversary as a Polish university in 1912.

Volume 5 of *Nauka Polska* being devoted especially to the movement called *regionalism*, prominence has been given in it (and accordingly, in the notice in NATURE) to local scientific societies in smaller provincial towns; but the fact must not pass unmentioned that learned societies for the promotion of research existed and flourished through all the vicissitudes of foreign rule in the 19th and early 20th century in such important centres of Polish life as Cracow, Warsaw, Poznan (Posen), Lwow (Lemberg), and Wilno.

Readers of NATURE before the War must have been familiar with the names of such Polish scientific workers as Smoluchowski in the field of physical science, Natanson in natural philosophy, Cybulski in physiology, Marchlewski in chemistry, Zarembka in mathematics, Nussbaum-Hilarowicz in biology—to mention only a few. Some of these men continue their work in the new Poland after the War. Others—like the lamented Smoluchowski—have since been taken from us, but new men are stepping into the breach, year in year out, from among the 40,000 university students of the new Poland. It is surely a proof of zeal for scientific research under the great difficulties which all countries experience after the War, and of which devastated Poland has more than her share, that of about 100 papers read at the International Geographical Congress in Cairo in 1925, no fewer than 22 were by Polish authors.

The writer of the notice in NATURE refers to the handicaps created by "restricted finance", but it is a source of pride and gratification to every Polish scholar and scientist that restrictions in the Polish budget have been exercised mainly in departments other than that of education and the endowment of research: this section of Polish State expenditure, in fact, has never ceased to increase in proportion to the rest since Poland has come into renewed existence, and it represents upward of one-sixth of the total expenditure of the State in the current administrative year. With State assistance on a large scale supplementing the private efforts in the way of the organisation of research in Poland, many new institutions have arisen since the War, such as the Geological Institute in Warsaw, which has done very useful service to the nation and to science in mapping out the mineral resources of Poland.

May I mention, finally, that Polish research bodies, like the Academy of Sciences at Cracow, regularly publish abstracts of the research work of their members in the shape of French, English, and German bulletins, and that English, in particular, has always figured rather prominently in the publications of the natural science section of the Academy.

Electric Discharge in Gases at Low Pressure.

A PAPER by Mr. McCurdy in the *Phil. Mag.* for November 1924 has recently come to my notice, and I shall be glad if space can be afforded me to correct certain statements made in it regarding the results of my work. I have also read with great interest the joint paper by Messrs. Compton, Turner and McCurdy in the *Phys. Rev.* for December 1924, and wish to

make a few comments on the subject now, leaving a further discussion of the result of my work on the nature of electric discharge through gases at low pressure for the Indian Science Congress to be held in January next.

Mr. McCurdy's information that my experiments under Sir J. J. Thomson pointed to the conclusion that striations cannot be obtained in pure nitrogen is, I regret to say, not correct. Not only did I get striations in pure nitrogen, but even in carefully purified helium—the purity of the helium being unquestionable—striations could be obtained. In argon, the absolute purity of which was not very carefully tested, remark-

FIG. 1.

able striations could be obtained. The accompanying diagram (Fig. 1) illustrates three argon striations, each consisting of two entirely detached parts, one the pink spherical glow showing the red spectrum of argon, and the other the bluish-green convexo-concave glow showing the blue argon spectrum. These two glows, however, appear connected to each other at higher pressures by a faint glow.

In fact, after having worked with pure hydrogen, helium, neon, argon, nitrogen, oxygen, chlorine, iodine, I came to the conclusion that striation can be produced in all pure gases, though the ranges of pressure and current density in the discharge tube suitable for the production of striation vary widely for different gases. I must confess that I did not try the effect of discharge in pure mercury vapour, but indirectly, by introducing traces of mercury vapour in pure unstriated helium discharge, I did get beautiful and well-defined mercury striations which began to appear one after the other from the cathode end of the positive column with increasing amounts of mercury vapour.

A careful study of the discharge in pure helium under different conditions and with the help of the rotating mirror points to the conclusion that the phenomenon of discharge is essentially intermittent, and that the conditions at the cathode and anode are of the same kind but of different intensity. It means that the positive ions and electrons or negative ions are ejected from the electrodes in regular pulses and move in opposite directions with different velocities. On this view the space charge or concentration gradient, as stated by Prof. Compton and others in their paper, can be easily understood.

The experiments cited to confirm the theory that a reduction in the concentration of the excited atoms helps the formation of striations do not appear to be conclusive. For example, the selective reduction of W_2O_3 can also be easily explained by the fact that the concentration of ions and electrons in the luminous region is greater than in the darker regions, and that, due to the consequent effect of more frequent elastic collisions and to the existence of potential gradient between the axis of the discharge tube and the glass walls, more dissociated hydrogen ions reach the glass wall in the region of the striations than of the dark spaces. Then again, even granting that the suggestion of striations noticed with increasing quantities of helium contamination in mercury was due to impurities and not a real effect, the conclusion drawn from the effect produced by helium, which is an inert monatomic gas of high ionisation potential, is inconclusive unless a comparative study of the effects of the addition of an electronegative gas and of pure nitrogen in similar circumstances is made.

I believe, however, that a decrease in the concentration of the excited atoms and in the mobility of the negative carriers—both effects very likely produced by the presence of negative ions—help to bring out well-defined striations, especially when the electro-negative and the electropositive ions have strong chemical affinity for each other.

I shall now endeavour to publish the account of my work, as I have finally given up all hopes of getting suitable opportunity to perform further experiments on the subject done in the Cavendish laboratory between 1920 and 1922.

A Revision of the Structural Formula of Glucose.

HITHERTO the balance of evidence as to the glucose structure has favoured the adoption of a γ -oxide ring formula (II.) which it is now customary to describe as a butylene- or 1:4-oxide structure. The property of mutarotation of sugars and the analogy which has been drawn between reducing sugars and their α - and β -methyl glucosides led to the abandonment of the older aldehyde formula (I.) for glucose in favour of (II.).

Whilst chemists have accepted the second of these formulæ as consistent with the experimental facts, yet it must be acknowledged that no direct proof of this structure has ever been advanced, and thus the allocation of a constitution to the commonest hexose rests mainly on the supposed analogy of the sugar with its related lactone, namely, gluconolactone.

In the aliphatic section of the Annual Reports of the Progress of Chemistry for 1924, published by the Chemical Society, the present writer expressed the opinion that current views regarding the formula of glucose would probably require revision. Meanwhile new evidence has been contributed by investigations conducted in these laboratories, and will shortly be published in detail, showing that normal tetramethyl glucose gives a δ -lactone on oxidation, whilst the corresponding γ -lactone is derived from the γ -sugar.

These results necessitate the adoption of the following constitutional formula for ordinary glucose:

In this formula the oxide ring shown in (II.) is displaced from the butylene-oxidic or 1:4 position, and

the attachment is that of a six-membered ring—that is, a 1:5 or amylenic oxide; and as this has been shown also to apply to galactose, mannose, xylose, and arabinose, the generalisation is reached that all aldoses exist normally as amylenic oxide forms. The γ -sugars of the aldehyde type must be regarded as butylene oxides.

Since glucose is an essential unit in most of the natural carbohydrates such as cane-sugar, maltose, lactose, starch, cellulose, it follows that the constitutional formulæ of these substances must undergo revision in the same sense.

Compton's Theory of X-ray Scattering.

READERS of NATURE may be interested in a short account of two experimental tests of Compton's theory of scattering which at present are being carried out here. Both of these tests deal with the total energy of the recoil electrons produced by hard X-rays.

One method is to compare the ionisation produced by the rays in very small (0.5 cc) air-ionisation chambers of different light substances (pure metals and salts). The ionisation in such small chambers is due solely to the secondary electrons from the walls. If these secondary electrons all had been of the photoelectric type, their number and therefore the ionisation would have been proportional to the third power of the effective atomic number of the wall substance. Thus, for example, the ionisation in a magnesium chamber should have been $8 \left[\left(\frac{12}{6} \right)^3 \right]$

times larger than the ionisation in a graphite chamber. Experiments show that for hard X-rays the ratio is considerably smaller, decreasing rapidly for decreasing wave-lengths. For the hardest X-rays which we have produced, the difference between the two chambers is only about 15 per cent. For the γ -rays there is no measurable difference. This decrease is due to the production of the recoil electrons, the energy of which is independent of the atomic number, and, as I have shown (Proc. Nat. Acad. Sci., 10, p. 441, 1924; *Zeit. für Phys.*, 29, p. 374, 1924), this energy can readily be determined by such measurements. For very hard X-rays ($\lambda < 0.15 \text{ Å.U.}$) our experiments verify Compton's theory to within experimental errors, which may amount to about 10 per cent.

In the second method, we measure the true absorption of hard X-rays in light substances like water. Under our experimental conditions, this true absorption is practically due solely to the production of the recoil electrons. The method consists in measuring the reflection of a very wide bundle of approximately parallel (and homogeneous) rays from the surface of a large mass of the substance, and measuring also the intensity of the rays at different depths under the surface. The difference between the incoming and the reflected energy must equal the energy absorbed in the substance, this amount being obtained by multiplying the average value of the intensity in the substance by the coefficient of true absorption. By introducing a correction for the photoelectric absorption, the absorption corresponding to the production of the recoil electrons is thus derived.

For water and very hard X-rays ($\lambda < 0.15$) we here also verify Compton's theory to within the experimental errors (about ± 10 per cent). (Compare *Phys. Rev.*, 25, p. 581, 1925.)

a marvellous event due to certain conditions which have never since been duplicated.

Similarly the primitive coelenterate, presumably a sponge, gave rise to ancestral Cnidaria still within the pre-Cambrian. Never since has the sponge given rise to anything but the sponge, but the phylum has continued to exist and to differentiate within seemingly fixed bounds. Before the close of the pre-Cambrian all the phyla of Invertebrata arose successively in this manner. Possibly we may include the vertebrates, although they have not yet been found so far back in time. These are well-known principles, but reiterated here because I think that they are not always given their true value.

I would emphasise—the origin of phyla as great events in geological history, the crowding of these events into the pre-Cambrian, the continuation of ancestral stocks, and their failure ever again to give rise to new phyla. It would appear, further, that higher phyla have not developed through highly specialised genera of lower phyla. For the invertebrates this is evident in the appearances of all the phyla in the pre-Cambrian; for the vertebrates, in the first place nothing is known with certainty, and in the second place the various phyla appeared long before high specialisation was attained by the ancestral stock. Amphibia arose from primitive Devonian ganoids, not from highly specialised teleosts; reptiles were derived from early Permian stegocephalians, not from highly specialised Anura or Urodela. The eutherian mammals appeared with startling suddenness in the basal Eocene, and before the close of the period had developed into all the great classes.

Evolution in the phyletic sense is not a gradual process, not uniformitarian, but marked by great events in time. Specialisation and consequent fixation of characters are adverse to phyletic differentiation.

It is apparent that phyla can arise only through genera and species. How far the phyletic principles may apply in the lower taxonomic ranks is an interesting question, the consideration of which would unduly extend this address. I would venture to state, however, that close adaptation (high specialisation) is likewise inimical to the production of new genera and species. Further, I believe that close adaptation is the main cause of extinction.

Let us assume the existence of an organism *perfectly* adapted to its environment. Is it not a safe conclusion that *any* change in environment must result in the death of such organism? That there is now or that there ever has been a perfectly adapted animal is extremely doubtful, but all animals must be more or less adapted or they could not exist. It may be stated that *the margin between perfect and necessary adaptation* is the zone in which organic evolution is possible; further, that the nearer an animal approaches perfect adaptation, the more liable it is to extinction on the advent of changed conditions. This conclusion is in accord with the generally recognised fact that in many instances highly specialised animals have suffered sudden extinction; it is also in accord with the general observation that the geological record is one of extinction and replacement in so far as species and even higher taxonomic divisions are concerned.

The great weight of geological evidence points to the

supplanting of one species by another, not to the transformation of species into their successors. A single transformation sequence may be regarded as sufficient to establish the principle, but an adequate explanation must be given of the failure of vertical seriations in the great majority of cases. This explanation is not yet forthcoming, and its lack stands as the chief item in the *contra* account of the balance sheet of evolution.

It is to the unfavourable changes that we must look for an explanation of the more deeply seated organic evolution, and by unfavourable I mean adverse to the present condition of the animal in that it is forced to further adaptation. A change of this kind is not of necessity *adverse to life*; it may even be stimulating. The animals towards the margins of a colony, by reason of their less perfect adaptation, may in a few instances survive an unfavourable change. The first impulse of these survivors will be to escape by flight, and thereby diminish the fatal suddenness of the change and thus achieve adaptation.

The new species would arise rather suddenly with but few individuals of the transition stages. Arrived at a favourable habitat, migration would cease, multiplication would ensue, and closer and closer adaptation would be achieved. Eventually an approximation to perfect adaptation would render the new species liable to extinction on the recurrence of unfavourable conditions.

This explanation of the common failure of vertical seriations emphasises migration as a factor in evolution and leads to the conclusion that transitional stages are few in number, scattered over wide geographical extents, and disposed in stratigraphically oblique lines. Barrell's "diastems," to be referred to later, support this explanation of abrupt changes in the faunas.

THE AGE OF THE EARTH.

The mysteries of time and of space have long been subjects of profound contemplation and scientific inquiry; they are intimately connected with the destiny of man and bring him into touch with the infinite. High is the cultural value of the mere contemplation of infinity, and of supreme importance is any light that may be thrown on a problem long regarded as beyond human comprehension. In recent years the theory of relativity has opened to the mathematically trained mind a possible avenue to a solution, but to most geologists this avenue is a closed road.

The determination of the actual age of the earth has long engaged the attention of philosophers and scientists, and various widely divergent estimates have been made by approaching the subject from different points of view.

Kelvin, Tait, King, and other great physicists but a few years ago allowed the geologist a maximum of 40,000,000 years for the age of the earth. Recent studies on radioactive minerals have induced the same school to raise the figure to 1,710,000,000 years, a *volte face* that emphasises the danger incurred by "the dictatorial hierarchy of exact scientists" in raising a mathematical structure on an insecure foundation.

The chief methods of determining the age of the earth other than those based on radioactivity, are: the rate of decline of solar energy, the gradient of earth temperature, the quantity of salt in the seas, the rate of organic

differentiation, and the rate of denudation of lands and of accumulation in the seas in relation to the known thickness of strata made throughout the geological ages.

The determination of age by means of radioactivity depends on the fact that uranium and thorium break down into lead and helium, and that the rate of this disintegration is known. The time required for half a given amount of these elements to break down is known as the half-value period. This period, according to Gleditsch, can be calculated to within 2 per cent.; for radium it is 1660 years and for uranium 6×10^9 years. An atom of uranium breaks down into one atom of lead and eight atoms of helium; if the content in these elements can be measured and compared with the quantity of unaltered uranium in an equal volume of the mineral, it is evident that the age of the mineral can be deduced.

Lyell long ago demanded 240,000,000 years for organic differentiation, and Darwin thought 200,000,000 too short for the purpose. On stratigraphic evidence, Barrell considered 250,000,000 a reasonable estimate for the duration of geological time since the pre-Cambrian.

The history of the subject shows that high figures were originally proposed by geologists and that, later, they tried to lower their estimates under the influence of the shorter time allowed by the physicists. More recently, the greater figures endorsed by the physicists permit the geologist ample time for his processes; both lines of inquiry are now pointing to the same result—higher and higher estimates of the immense antiquity of the globe.

Intimately connected with the estimation of time are the rates of erosion of old rocks and of deposition of new. Herein lies the most dependable geological means of determining the duration of the periods; nevertheless, there are serious difficulties to overcome, among which may be mentioned: variations in the rate of decay under different conditions, variation in the rate of deposition, and the occurrence of unrecorded intervals either evident or obscure.

The rate of erosion has received much attention, but as this factor is obviously dependent on the shape and condition of the land surface, its average for all time is difficult to estimate. Barrell considers that denudation by solution lowers the land surface one foot in 30,000 years, and that mechanical degradation accomplishes this result in 13,800 years. The two forces acting together require 9000 years to effect one foot of erosion.

Barrell's estimate of 250,000,000 years since the beginning of the Palæozoic was arrived at by a study of details of deposition under the hypothesis of rhythms in geological time. According to this author, time is to be measured by rhythms or pulsations, the greater rhythms having shorter rhythms imposed upon them. The longer are to be measured in terms of the smaller, and the smaller in terms of years. A single rhythm is an erosion cycle and small partial rhythms are superimposed on it. Present erosion and sedimentation owing to the Pliocene-Pleistocene uplift is unduly high, with the result that estimates of time based on the present rate of erosion are much too short. Barrell would further increase the time by restricting the area of deposition to the zone immediately below the local base level, and making the accumulation dependent on

upward oscillations of the base level or downward oscillations of the bottom.

In connexion with the rate of sedimentation and its bearing on the age of the earth, it is apparent that the intimate structure of the stratified rocks must be looked to for data bearing on the problem. To this end the character and mode of formation of these rocks are now receiving an increasing degree of attention. A better understanding of sedimentation is being obtained by direct observation on the formation of modern sediments, determination of the precipitating value of algae and bacteria, studies on coral reefs, deep-sea investigations, studies on colloidal solutions, investigations of chemical deposits, and a better appreciation of the value of facies and vegetal terrestrial deposits. Direct investigation of the rocks themselves is leading to an increased use of the petrographic microscope and of analytical methods. Secondary features of stratified rocks are receiving greater attention, horizontal transitional stages are better understood, and the relationship of strata to sea invasions has led to a fuller appreciation of the value of palæogeography.

THE ORIGIN AND INTERIOR OF THE EARTH.

The question of the earth's origin is evidently closely related to the problem of its age. Although geologists are inclined to disclaim this aspect of the subject, I feel that it cannot be disregarded under the title of this address. The interior of the earth is beyond direct observation; the deepest mines and bore-holes scarcely penetrate the outermost skin. Certain fundamental facts, however, may be taken as established. The interior is hot, rigid, and heavy (sp. gr. 5.6 as compared with 2.7 for the known exterior); the accessible exterior is composed of elements common to the universe. Beyond this all is vague and speculative.

It is worthy of particular emphasis, however, that while the earth as a whole acts as an almost perfectly rigid body, the external envelope with which we are familiar is by no means rigid. Adjustments have taken place throughout all geological time, and I need not quote evidence that they are still taking place. The acquisition of perfect rigidity by the globe is to be regarded as a tremendous calamity. This condition attained, the universal deluge is within sight geologically speaking, and the end of the present order of things must inevitably ensue. Earthquakes, therefore, are not to be regarded as unmixt calamities; they are evidence that the fatal total rigidity has not yet been attained.

It might be asked if there is any evidence in geological history of an approach to a condition of total rigidity or of a tendency in this direction. There can be little doubt that pre-Cambrian events were on a scale seldom, if ever, attained in later time. Cambrian and Ordovician transgressions of the sea were also on a grand scale, but later movements, on the whole, seem to have been smaller and more local in their expression, although there were notable exceptions as the Tethys sea in Europe, the great invasion of the Coloradoan geosyncline in Upper Cretaceous time in North America, the tremendous volcanic activity of the Miocene, and the grand epoch of mountain-building in the Pliocene and Pleistocene.

The general conclusions seem to be that the earth is not showing a trend towards rigidity, but that earth movements and vulcanism are becoming less profound in scope and less widespread geographically, the average of activity being maintained by more frequent recurrence.

EARTH MOVEMENTS AND ADJUSTMENT.

The causes of earth crumpling and the dynamic laws which govern the phenomena are subjects well within my theme, but their consideration would lead me to undue length. Earth movements, of necessity, are bound up with theoretical considerations of the earth's interior. Whether earth crumpling is due to loss of terrestrial heat and consequent contraction of the nucleus, or whether the modern concept of isostasy offers a better explanation, there must be a downward limit to terrestrial disturbances. This limit has been placed at 113.7 kilometres and termed the "depth of compensation."

It is obvious that a consideration of this subject would lead to a discussion of land forms and their influence on human activities—definition of nationality, physiographic control, distribution of faunas, and countless other effects, all of which extend beyond the realm of technical geology and form part of a general education if they are not "cultural" in the narrower sense. There is, however, one great lesson to be derived from the study of earth movements that bears on the general scheme of things and is worthy of especial mention—the marvellous continuity of conditions.

The diameter of the earth is about 8000 miles and the maximum of relief of the lithosphere about eleven miles, approximately 0.14 per cent. Oceanic waters have filled the depressions and continental masses have risen above the water-level—a condition that has maintained throughout all time in the opinion of most geologists. The present area of the land is 27.7 per cent of the whole terrestrial surface, and the average height above sea-level of the continental masses is only 2120 feet according to de Lapparent. It is apparent that the actual volume of that part of the lithosphere which projects above sea-level is extremely small when compared with the volume of the whole globe.

It is well known that the power of erosion is sufficiently great to have reduced this relatively small mass to sea-level time and time again throughout the long course of the geological ages. Nevertheless, it is confidently believed that this result has never been entirely achieved. Rejuvenation has kept pace with erosion throughout the hundreds of millions of years that the earth has endured. In my opinion this marvellous nicety of adjustment between two great sets of opposing forces is one of the major lessons of geology. Is it a mere coincidence or is it evidence of design?

CLIMATE.

Climatic change must be regarded as an ever-present factor. It is highly probable that variation in climate will greatly affect the activities of the human race within a measurable number of years, and it is not impossible that the sites of our present centres of civilisation will be buried under glaciers and that a new civilisation will occupy, under a genial climate, the present inhospitable regions around the poles.

Despite the changes in any given locality, the continued existence of life is sufficient evidence that the whole globe has not experienced, from the earliest geological time, any very great universal change in climate. Grüner has proved to the satisfaction of most geologists the existence of algæ in the Keewatin of Minnesota. The great masses of limestone with disseminated graphite of the Grenville are at least suggestive of life, and Moore has brought forward convincing evidence of algæ in the Animikie of Belcher Islands in Hudson Bay. Both the Archæozoic and the Proterozoic, therefore, were warm enough to permit organisms to exist despite the intervening event of an ice age in the Huronian.

Wonderful have been the changes in climate and far-reaching their effects, but truly marvellous has been the continuity of a range of temperature permitting the existence of life from the very dawn of earth history to the present moment. Nothing short of a cosmical catastrophe can alter a condition that has maintained for nearly two thousand millions of years. Surely if culture is the cultivation of the spirit, the contemplation of geological climate should lift the mind above the mere material into the realm of the philosophical and the spiritual. If the continuity of the observed range of temperature is due to a single factor—solar energy—the endurance of that energy is a marvellous thing. If the observed climatic continuity is a composite result due to various sources of energy, it is still more marvellous.

THE STUDY OF GEOLOGY.

Whatever satisfaction is to be derived from the acquisition of knowledge, there is always a discouraging factor in the realisation of our limitations. Owing to the complex nature of the subject and the vast number of facts involved, the study of geology is peculiarly effective in this respect, and cannot but tend to a humble attitude of mind. Another potent influence to this end is the realisation of the mistakes that have been made, even in the basic principles of the science. From the fantastic theories of the cosmogonists arose eventually the doctrine of catastrophism; this conception yielded to uniformitarianism, and to uniformitarianism was added the doctrine of evolution. Le Conte described Darwin as a uniformitarian evolutionist. To-day uniformitarianism is being questioned seriously from both the inorganic and the organic points of view. We are swinging back to a conception of a milder catastrophism variously expressed as rhythm, diastrophism, and so on. The necessity of drawing conclusions from doubtful or insufficient evidence is an ever-present antidote for dogmatism. Many of our conclusions are merely inferences subject to revision in the light of further evidence.

To humbleness and caution I would add a conviction of theism as a result of the study of geology. I fear to venture on dangerous ground, but I must be allowed the opinion that materialism offers no adequate explanation of the wonders of geology. With revealed religion I am not here concerned, but I believe that the inconceivably long gradient that has led ever upward to the mentality of man has not been traced without design, and I see no reason why that gradient should terminate. I look, rather, to its upward continuation to even greater heights beyond.

Some Issues in the Theory of "g" (including the Law of Diminishing Returns).¹

By Prof. C. SPEARMAN, F.R.S.

THEORY OF "G."

THE following communication treats of certain points in a theory which has become known as that of Two Factors or of *g*. At the present time this theory has undergone very elaborate development. The mental testing from which it originated lay at first as a foreign intruder in the midst of general psychology. Its opponents—and these were not few—regarded it as an excrescence that should be forthwith cast out; and even its best friends wondered how the general psychology was ever going to assimilate it. But, seemingly, neither of these solutions is happening to any great extent. The mental testing has waxed larger and established itself more firmly than ever *without* much assimilation with the current general doctrines; indeed, it seems more likely, cuckoo-wise, to eject *them* from the psychological nest. In particular, the theory of *g*, which arose from the mental tests, has now managed to spread itself over the whole of the cognitive side of psychology, and not impossibly it will soon extend its scope over into the supplementary or conative side.

For the present I do not propose to depict the whole elaborate theory of *g* even in outline. Such an attempt is reserved for a work that will appear shortly. But a very few words may be allowed here to indicate its essential foundation as unwaveringly preserved from the very beginning. This consists in the theorem, that the measure of *every different ability of any person can be resolved into two factors, of which the one is always the same, but the other always independent*. Suppose, for example, that any person undergoes a mental test and obtains seventeen marks for it. The theory asserts that this can actually be divided into two parts, say eleven and six, such that (on reduction to comparable units) the eleven re-occurs for this person in every other test however widely different, whereas the six is each time replaced by some other number independently.

The establishment of this doctrine falls into three distinct phases. The first is to ascertain what are the conditions under which the measures of any ability admit of such division into two factors. We may note that this phase has often been erroneously called an assumption or hypothesis. It is really nothing of the kind, but simply a mathematical demonstration. Given the said conditions, then the divisibility into such two factors must necessarily occur, just as, given that a triangle has all its angles equal, then it must needs also have all its sides equal. The second phase is to find out where, if at all, the conditions are actually fulfilled. Again, no assumption or hypothesis of any kind is involved; the matter is nothing more than observation of fact.

Then comes the third and last phase, that of supplying the factors with some plausible interpretation. Here the most cautious procedure, and one that goes not an inch beyond what has really been proven, is simply to denote these factors by the non-committal letters *g* and *s* respectively. Any interpretation going beyond this can only, in our present state of knowledge, have a provisional value; it can serve to inspire further

investigation, by which it will assuredly suffer much modification itself. With this reservation, then, the hypothesis at present seeming most helpful and suggestive is that the *g* measures something of the nature of an "energy" derived from the whole cortex or wider area of the brain. Correspondingly, the *s*'s measure the respective efficiencies of the different parts of the brain in which this energy can be concentrated; they are, so to speak, its "engines." Whenever the mind turns from one operation to another, the energy is switched off from one engine to another, much as the power supply of a factory can be directed, at one moment to turning a wheel, at the next to heating a furnace, and then to blowing a whistle.

RECENT CONFIRMATION.

So much to serve as a general description of the doctrine. I will now bring to your notice some recent work whereby its foundations have received additional strengthening, both on the side of mathematics and on that of actual observation.

To take the former first, the earlier researches had only shown what conditions are *necessary* for the divisibility into the two factors. Later investigation has proved that these conditions are also *sufficient*. In other words, we now know, not only that under the said conditions the divisibility into two factors may possibly occur, but also that it inevitably must do so. I stress this point because some of the recent writing on the subject appears to make the contrary and mistaken statement that, even when the conditions are satisfied, still the divisibility either may or may not ensue.

As to the precise nature of these conditions, they are based upon the coefficients of correlation. Such coefficients, as is now generally understood, consist in numbers that indicate just how closely any two abilities or other characters tend to vary in proportion to one another. They are usually symbolised by the letter *r*. Thus, r_{12} would denote the degree that any ability 1 tended to vary from individual to individual proportionately to some other ability 2. Now, the conditions for the divisibility into the two factors reduce themselves to the simple equation:

$$r_{12} \cdot r_{34} - r_{13} \cdot r_{24} = 0.$$

Here the value on the left is called the tetrad-difference. When such tetrad-differences remain equal to zero throughout any set of abilities, whichever of them may be taken as 1, 2, 3, and 4 respectively, then and then only, each of these abilities can be divided up into two factors such as we have described. Should any one ask *why* this particular equation should have the virtue of necessitating such a divisibility, I can only answer that it is but one out of all the miracles of mathematics. I never cease to be astonished at it myself. For further elucidation, reference must be made to the mathematical proof (Proc. Roy. Soc., 1923).

So far we remain in comparatively smooth waters. The chief difficulty arises when we turn to what are known as the errors of sampling. Suppose you wanted to know whether a field of potatoes was bearing a good crop. You walk about, pulling up a plant here and

¹ Presidential address delivered at Southampton on August 27 before Section J (Psychology) of the British Association.

there This gives you some approximate knowledge, but not an exact one. For all you can tell, you may have been exceptionally lucky or unlucky in your selection. The degree of discrepancy between the average size of the potatoes actually pulled and that of the whole field is your error of sampling. Now, just the same befalls any coefficient of correlation between two abilities. You want to know how closely these two go together with people of some general class. You pick out, say, 100 of these people; but just in this 100 the correspondence between the two abilities may happen to be rather higher or lower than on an average throughout the entire class. Your coefficient of correlation will have an error of sampling; and our preceding tetrad-difference, being made up of correlational coefficients, will have one also.

Now, the latest advance in the theory of g consists in showing the general magnitude of the tetrad-differences that will arise from the sampling errors alone, even when the true magnitude is always zero. This value of the tetrad-differences to be expected merely from sampling was published last year (*Brit. J. Psychol.*).

Having got this theoretical value, there remains the momentous step of comparing it with the median value which is actually observed. The theory of g stands or falls according as these two values are or are not found to agree.

This step so fraught with fate has now been taken. To avoid all danger of personal bias, no work of my own was chosen for this crucial decision, but that of an investigator who, more than all others, had shown himself unsympathetic with the doctrine of g . Here is his table of correlations as published by himself:

Test	1	2	3	4	5	6	7	8	9	10	11	12	13	14
1 Completion		98	94	79	62	91	71	54	78	88	55	42	33	25

9 Learn. pairs	78	73	73	42	39	59	39	35		69	36	29	26	09
10 Recog forms	88	74	71	56	51	66	47	49	69		44	37	34	28
11 Scroll	55	52	53	45	39	54	51	34	36	44		31	19	27
12 Compl words	42	43	40	29	59	31	57	56	29	37	31		21	07
13. Estim length	33	26	28	38	25	28	17	25	26	34	19	21		24
14. Drawing length	25	25	21	48	22	19	25	25	09	28	27	07	24	

To work out all the tetrad-differences was no light undertaking, since they run to the number of 3003. The calculation of these was entrusted to the competent hands of Mr. Raper. When all was reported ready we met, I carrying the "probable error" of the tetrad-differences—that is, the median value that should by theory be expected to arise from sampling alone, he bringing the average value of the 3003 tetrad-differences actually derived from the above table. My number was 0.061. His was 0.074; this, in order to get from the average to the median, had to be multiplied by the well-known constant 0.845, whereby it came finally to 0.062.

It may be of interest to survey the entire frequency distribution of the values concerned. The dotted curve (Fig 1) shows the relative frequencies that should be expected from the sampling errors alone. About half should lie between a and b ; extremely few beyond

c or d . The continuous rectangles show the relative frequencies that actually occurred. A better agreement of a theoretical frequency curve with one of actual observations does not, I venture to say, exist throughout psychology, or perhaps even throughout statistics.

The preceding result may be instructively compared with another one. The doctrine of Two Factors, as is only proper, has had to make its way in the face of strong resistance. But the latter has curiously adopted two contrary lines of defence. One is to question whether the mathematical criterion would really be satisfied by actual observation; and this doubt, I hope, has been met by the facts just cited. But the other opposition has instead asserted that *any* ordinary table of positive correlations would naturally satisfy it, so that such satisfaction must be devoid of peculiar significance. Recently this second line of opposition

has acquired much greater vitality, in that a table of correlations has now been brought forward as an actual example, it is not derived from mental but from physical traits, and yet, it is said, exhibits a quite similar character. Here is the table:

	1	2	3	4	5	6	7	8
1 Area of ossification		88	60	62	43	31	25	26
2 Ratio of ossification	88		52	58	41	21	24	29
3 Height	60	52		69	44	51	45	11
4 Weight	62	58	69		65	39	40	83
5 Chest girth	43	41	44	65		59	36	69
6 Lung capacity	31	21	51	39	59		46	26
7. Strength of grip	25	24	45	40	36	46		14
8 Nutrition	26	29	11	83	69	26	14	

Let us, then, look at the median tetrad-difference derived from this table and compare it with the probable error to be expected from sampling alone; the respective values are 0.089 and 0.011; that is to say, the actually observed value is no less than eight times greater than what theory demands. Here again we can examine the whole frequency distribution.

The explanation of the figure (Fig. 2) is the same as in the preceding case of Simpson (Fig. 1). Between the curve showing the values to be expected from the errors of sampling and the rectangles showing those actually observed there is this time no agreement whatever.

LAW OF DIMINISHING RETURNS.

So much for the strengthening of the doctrine. I will now proceed to describe a rather curious matter that has arisen in the course of its elaboration

Since the very beginning it has been known that the two factors, *g* and *s*, the energy and the engines, may have widely different relative importance, according to the particular mental operation involved. With some operations the superiority of one person over another is preponderantly decided by their respective amounts of the energy. With other operations, on the contrary, the dominant factor is the engine.

Subsequent research, moreover, has been gradually outlining the cases which incline in one or the other direction. Thus the energy is in general more important for operations that are composite, the engines for those that are monotonous. This is natural enough. The composite operation really involves several different engines; the superiority that an individual may happen to have in any one of them will tend to be neutralised in the average of them all; but a superiority in the energy will make itself felt in each, and thus obtain cumulative influence. Again, the energy is less and the

FIG. 2.—Tetrad-differences of A. Gates (115 subjects)

engine more influential whenever the operation depends much upon the efficiency of some sensory or motor apparatus. This, too, is natural enough; for such apparatus obviously constitutes a part and parcel of the engine. Yet again the energy has been found to lose in importance as compared with the engine in proportion as the operation tends less to create new mental content and more to reproduce old.

The point which I wish to bring forward in this place is that the relative influence of the energy and the engines changes largely with the class of person at issue. The most drastic example of this is supplied by a comparison between normal children and those who are mentally defective. The work of Abelson may be quoted, where the same tests were applied by the same experimenter to both classes. The correlations obtained for the two respectively are as follows:

NORMAL CHILDREN. (78 CASES)												
	1	2	3	4	5	6	7	8	9	10	11	12
1. Opposites . . .	75	78	71	62	64	72	78	57	40	46	33

6. Observation . . .	10	91	88	77	73	76	83	71	86	59	65	
7. Memory form . . .	10	85	68	84	90	76	65	67	70	77	75	
8. Interpret. pictures	10	76	92	67	68	83	65	74	80	80	59	
9. Geometrical figs .	98	85	74	76	88	71	67	74	65	60	62	
10. Discrim. length .	94	87	78	81	65	86	70	80	65	51	45	
11. Tapping	94	70	76	73	78	59	77	80	60	51	45	
12. Strength of grip	79	72	67	55	68	65	75	59	62	45	61	
Mean = 0.782.												

All round, obviously, the correlations are much smaller in the case of the normal children. This indicates that with these the influence of the energy has gone down and that of the engines has correspondingly gone up.

Compare next young children with those that are older. Here I may quote from the admirable work of Prof. Burt. Applying his test of reasoning to numerous children of different ages, he obtained the following correlations with the estimates of the teachers (in general, the older children show smaller correlations):

Ages . . .	10-11	11-12	12-13	13-14
Correlations .	78	81	64	59

No less marked is this tendency on comparing children with adults. As examples may be taken the correlations obtained by Otis and Carothers respectively for what appear to have been similar tests in each case.

Test	Correlations with <i>g</i> , Otis, grades IV-VIII	Carothers, students.
Analogies	0.84	0.71
Completion	0.88	0.53
Directions	0.86	0.45
Digits, memory . . .	0.41	0.22

Now these changes obviously follow a general rule. The correlations always become smaller—showing the influence of *g* to grow less—in just the classes of person which, on the whole, possess this *g* more abundantly. The rule is, then, that the more energy available already, the less advantage accrues from further increments of it. This is a well-known property of engines in general. Suppose that a ship at moderate expenditure of coal goes 15 knots an hour. By additional coal the rate can readily be increased another 5 knots. By doubling the addition of coal, however, the additional knots will certainly not be anything like doubled. This relation is observed not only in engines, but also widely elsewhere. In the science of economics, for example, it is expressed in the well-known law of diminishing returns. A moderate amount of capital spent on a given piece of land will produce a certain return; but on adding further doses of capital the returns will not increase proportionately.

In our psychological case of different classes of persons there enter no doubt various complications which render the theoretical interpretation more dubious. Above all, there is the fact that the classes better endowed with *g* have usually undergone more or less selection. For example, the university students of Carothers had been cleared of the weaklings who could not matriculate. This in itself would tend to lower all correlations due to *g*. However, such facts would seem capable of accounting for only part of the phenomenon,

not for the whole. There remains enough over to suggest a genuine law of diminishing returns for mental as for material processes.

COROLLARY OF INDEPENDENCE.

The next and final point to be raised here is a corollary of what has been said. Since a great many abilities depend almost entirely upon the efficiency of the engines involved and this efficiency varies independently from individual to individual, we may conclude that these abilities themselves vary almost independently from individual to individual.

This theorem has, indeed, been called into question. Some authorities have asserted the existence of a general "sensory level" of ability, so that the persons who are successful at one kind of sensory performance will tend to be so at others also. Other writers have adopted a similar position as regards what they call "practical" ability; persons are taken to be either endowed or not endowed with this all round. But no such position would appear to be supported by the available definite evidence. Dr. McCrae, for example, has recently examined the correlations between different tests that have been entitled those of "performance." These, even among persons of comparatively low status, proved to be, in fact, almost independent of each other. Still more striking has been the result of a very valuable investigation by Mr. Philpott. He undertook to test the discrimination of length, a power which obviously possesses great importance in many spheres of industry. He wisely tested this discrimination in two different ways. First, he showed pairs of lines and made the subjects judge which was the longer; and then he gave them single lines and made them, in each case, draw another line as nearly as possible of the same length. As result, these two performances, that seemingly are but manifestations of one and the same power, turned out to be almost entirely independent. Those who were best at judging between the two lines already drawn did not, to any appreciable extent, excel at making a second line equal to a given one. Quite similar results were obtained for the discrimination of angles, as also for perceiving whether a line is straight or not.

Accepting, then, the conclusion that an immense number of abilities vary from one individual to another almost independently of each other, what is the practical result? Let us try to get a notion how such abilities of any person must be distributed in respect of excellence. By all experience, and also by statistical theory into which we cannot enter here, the great bulk of his abilities will tend to be mediocre; that is to say, they will be near the general average of his class. A fair number will be distinctly above this average, and a fair number below. A small number will be much above; and so also below. The whole frequency distribution will, in fact, have a bell-like shape similar to that which was shown by the curves of the tetrad-differences to be expected from sampling errors. At the extreme ends of the distribution will lie a very small number of performances for which the person is, on one side a genius, and on the other an idiot. Every normal man, woman, and child is, then, a genius at something as well as an idiot at something.

It remains to discover *what*—at any rate in respect of the genius. This must be a most difficult matter, owing to the very fact that it occurs in only a minute proportion out of all possible abilities. It certainly cannot be detected by any of the testing procedures at present in current usage, but these procedures are capable, I believe, of vast improvement.

The preceding considerations have often appealed to me on looking at a procession of the unemployed, and hearing some one whisper that they are mostly the unemployable. That they are so actually I cannot help concurring. But need they be so necessarily? Remember that every one of these, too, is a genius at something—if we could only discover what. I cherish no illusion, indeed, that among them may be marching some "mute inglorious Milton, some Cromwell guiltless of his country's blood." For these are walks in life that appear to involve a large amount of *g*. But I am quite confident that every one of them could do something that would make him a treasure in some great industrial concern; and I see no reason why some should not have even become famous, in such occupations, for example, as those of dancers, jockeys, or players of popular games.

Radiometric Measurements of Stellar and Planetary Temperatures.

By Dr. W. W. COBLENTZ, Bureau of Standards, Washington, D.C.

THE recent measurements of planetary radiation and planetary temperatures, especially of Mars, had their beginning in the first really successful tests at the Lick Observatory, Mt. Hamilton, California, in July 1914, when thermo-couple measurements were made on 112 celestial objects, including 105 stars, down to magnitude 6.7, and the planets Venus, Mars, Jupiter, and Saturn. (Bureau of Standards Sci. Paper, § 244, 1914.) The experimental procedure then employed, and the results obtained, have foreshadowed, in an unforeseen manner, practically everything that has been accomplished since then.

During the world strife and confusion that occurred in the meantime, nothing further was accomplished until the fall of 1921, when, at the invitation of the Lowell Observatory, I was given a further opportunity to try out a new method of measuring stellar tempera-

tures by means of screens of quartz, water, etc., which separated the incident radiation into components containing radiation of the following wave-lengths: 0.3 to 0.43 μ ; 0.43 to 0.6 μ ; 0.6 to 1.4 μ ; 1.4 to 4.1 μ ; and 4.1 to 12 μ . In this manner the distribution of energy in the spectra of 16 stars was determined, thereby obtaining for the first time an insight into the radiation intensities in the complete spectrum of a star.

From a comparison of the observed stellar spectral radiation components with similar data, calculated for a black body at various temperatures, it was found that the stellar temperatures range from 2500° to 3200° K for red stars, up to 14,000° K or even higher for blue stars, which is in good agreement with other methods of estimating stellar temperatures.

Since then Pettit and Nicholson, using similar thermo-couples and a transmission screen of water attached to

the great 100-inch reflector of the Mt. Wilson Observatory, have been able to study long period variable stars of visual magnitude down to magnitude 9.2 and temperatures below 2000° K. In the meantime, Abbot has succeeded in measuring the distribution of energy in the spectrum of a number of the brightest stars, and has obtained temperatures in good agreement with those previously observed by the writer, using a thermocouple and transmission screens. Furthermore, using the writer's radiometric measurements, and assuming that the radiation from these stars is similar to that of a black body, Stetson has computed stellar diameters which are in good agreement with those measured directly with an interferometer.

From the foregoing results it appears that the outlook for the thermocouple as a useful instrument in stellar radiometry is very promising: (1) as a device for estimating stellar diameters; and (2) for determining the temperature of stars that are too small to measure the spectral energy distribution directly, thus supplementing the work of Abbot. The only discrepancy is perhaps in the published measurements of the radiation from Sirius. There seems to be something elusive about this star. Back in 1914 it was on the list for measurement; but because of daylight and low altitude no attempt was made to measure it. In 1921 a series of radiometric measurements gave a water-cell transmission of about 70 per cent. (in Bur. Stds. Sci. Paper, § 438, is given the uncorrected value, 65 per cent.). This would indicate that the spectral type of the companion star of Sirius is lower than A—perhaps below type F or down to type K. Owing to an uncertainty in some recent radiometric measurements on this star, further work must be undertaken to disprove or verify these results.

The results of 1921 were so promising that the Lowell Observatory extended the invitation to continue the investigation in 1922, especially of planetary temperatures, in preparation for the opposition of Mars in 1924.

In all these measurements of planetary radiation, use was made of the 40-inch Lowell reflector with focal lengths of 220 inches and 640 inches; Mr. C. O. Lamp-land, astronomer at the Lowell Observatory, collaborating. The measurements of 1922 and of 1924 are in agreement in showing that the planetary radiation emanating from Jupiter and from Saturn, and transmitted by our atmosphere, is very small, while the planetary radiation from Venus, Mars, and the moon is, relatively, very intense. The radiometric measurements made in 1922 indicated that about 30 per cent. of the total radiation emanating from Mars is of planetary origin, as compared with 80 per cent from the moon. From the fact that the surface temperature of the moon is estimated to be considerably above 100° C., the writer estimated (Bur. Stds. Sci. Paper, § 460, 1922) that the temperature rise of the surface of Mars is considerable—perhaps so high as 10° to 20° C.

From the water-cell transmissions obtained by us in 1922, Menzel (*Astrophys. Jour.*, 58, p. 65, 1923), using Russell's formula, calculated the following temperatures: Venus, 50° C.; Jupiter and Saturn, -110° C.; and the moon, 120° C. From the water-cell transmissions of the radiation from Mars, observed on June 15 and 18, 1922, his calculations gave temperatures of -5° C.

and -9° C. respectively, the higher value being for the smaller receiver, which intercepted 0.4 of the diameter of the planetary disk. From the large temperature gradient observed in 1924, extending from the equator to the poles and the limbs of the planet, it is evident that the highest temperature, -5° C., is an average value, which should be corrected for latitude. This would raise Menzel's values to 5° C., or perhaps even higher, when corrected for non-black body radiation.

Using our data observed in 1924, Menzel has calculated an average temperature of -30° C. for the whole disk of Mars. The temperatures of the apparent centre of the disk ranged from -5° C. on the bright areas to 22° C. on the adjacent dark areas, the predominating values being 6° to 9° C. The true temperatures would be about 10° higher, or 15° to 20° C. The temperatures derived by this method of reducing the data are in good agreement with those obtained by three other methods, all of which indicate conclusively that the equatorial temperature of Mars, at perihelion, was considerably above 0° C.

The planet Venus is one of the most interesting cases met with in radiometric observations. The surface of the planet is hidden by clouds, and its period of rotation is undetermined. Hence the thermocouple radiometer appears to be a means of obtaining further information on this question. For it was found that not only does the illuminated crescent show the presence of considerable planetary radiation, but the unilluminated part of the disk also emits a large amount of infra-red rays. This raises the question whether the radiation from the dark side of the planet is owing to a rapid rotation. If the period of rotation is long (225 days), then it seems necessary to assume that the surface of Venus is still quite warm, although the highly selective condition of the planetary radiation at $8-12 \mu$ may perhaps be interpreted as due to radiation of the hot gases convected from the illuminated over the dark part of the planetary surface. However, since this involves distances of 800 to 1000 miles over the surface, it seems difficult to reconcile this assumption with the radiative properties of the gases which probably constitute the atmosphere of Venus.

An interesting and important observation is that the intensity of the radiation emitted from near the south cusp in the present position of the planet Venus—both for the dark and the illuminated regions—is greater than that emanating from corresponding points near the north cusp. This may be owing to differences in the surface conditions, as previously observed on Mars. Then, again, it suggests an effect of insolation due to inclination of the axis of rotation, analogous to seasonal changes on Mars and the earth. Further radiometric observations, at different presentations of the planet's surface to the earth, will be required to test this question. If this is seasonal, then it should be possible to establish the position of the axes of rotation of Venus.

From our data observed in 1924, Menzel calculated the following temperatures: Venus, 60° C.; Jupiter, -135° C.; Saturn, -150° C.; Uranus, lower than -185° C.; and the moon, 125° C. These calculations are in good agreement with those based upon our data of 1922, and they are in good agreement with Christiansen's theoretical calculations made long ago, in which he obtained the following values: Venus, 65° C.; Jupiter, -147° C.;

Saturn, -180° C.; Uranus, -207° C.; and Neptune, -221° C.

In the case of Saturn, the observations seem to indicate that the temperature is higher than can be maintained solely by the incident solar radiation. In other words, the interior of the ball of Saturn is still relatively hot. This is in agreement with the views expressed by Poynting twenty years ago, when he made his theoretical calculations of planetary temperatures, obtain-

ing 69° C. for Venus and -38° C. for Mars. As an average value for the whole disk of Mars, Poynting's calculation of -38° C. is in good agreement with our observed value of -35° C.

The observed temperature of the moon, 125° C., is in good agreement with the values assigned to it years ago, by Lord Rosse, 110° C., and more recently by Very, 150° C., by comparison of the lunar radiation against a black body.

Deinosaur Eggs.

By Dr. F. A. BATHER, F.R.S.

THE *Times* published on September 9 an interesting despatch from its Peking correspondent, giving further details of the discoveries in Mongolia by the expedition from the American Museum of Natural History, led by Mr. Roy C. Andrews. The fresh information about the fossil eggs attributed to dinosaurs suggests some comment.

Two of the recent finds are particularly worthy of note. One is a nest of twelve eggs almost perfectly preserved. The eggs were arranged in a circle, with the narrow ends pointing outwards; no doubt the broad end was, as in birds, that which first emerged, but in birds' nests this end of the egg is, as one would expect, directed outwards. Then the eggs are said to have been "in two layers of six each," those of the upper layer presumably alternating with those of the under one. This, if a correct description, suggests that the dinosaur scooped a basin in the sand, and perhaps covered the first layer with sand, as is the habit of the Nile crocodile.

The other find was a nest of five eggs, "smaller than those found two years ago, more elongated, and evidently the produce of another type of dinosaur. The shells are smooth, in contrast to the dimpled surface of the others, and very thin." Are they the eggs of a dinosaur at all? All as yet known have notably thick shells. These might be the eggs of a crocodile or a chelonian. Turtles' eggs are now being fossilised in just the same way in the sand-dunes of Western Australia.

The last question will have to be settled by the study of thin sections. It is strange how little was known two years ago about the structure of egg-shells, whether recent or fossil, of birds or of reptiles. Nathusius alone has studied thin sections of recent egg-shells, describing that of the moa in 1870, and that of a python in 1883. About 1870 also, some Cretaceous fresh-water sandstones in Provence yielded the bones of a reptile and some fragments of egg-shell. The latter and thin sections cut from them were re-studied in 1922 by Dr. Van Straelen and Mr. E. Deneyer of Brussels. The reptile is generally supposed to be some sort of dinosaur, and the eggs are assigned to it with some probability, made stronger by Dr. Van Straelen's later researches, of which a preliminary account was recently issued by the American Museum of Natural History. The following summary is based on the researches quoted and a few more general facts.

The egg of all birds and reptiles, when first formed within the body, is covered with a flexible membrane. At a large number of points in this membrane minute specks of lime appear. Round each of these specks

more lime is gradually added in successive layers like the coats of an onion, thus building up little spheroids. When these spheroids meet one another, they form a complete coating to the egg, so that further layers of lime can be laid down only on the outer side of this. The layers outside any one spheroid thus build up a pile of irregularly prismatic shape and connect irregularly with the layers of the adjacent piles or prisms. On the inner surface of the first-formed coat each spheroid appears as a little hillock or mamilla; so this is called the "mamillar zone." The outer layers form the "prismatic zone." Outside the latter some of the membrane may remain as a "cuticle."

In chelonians the egg-shell is very thin, being composed only of the mamillar zone, with gaps remaining between the spheroids. In snakes the shell is still thin; the prisms are there, but they do not always join up. In crocodiles the shell is thicker than in turtles and in most birds, but the prismatic zone is scarcely developed; spaces, in the form of canals of two sizes, are left at intervals between the spheroids, so that air can reach the developing embryo. All birds have a mamillar zone and a relatively thick prismatic zone. In the *Ratitæ* the shell is thick and the air-canals branch as they near the outside, each ending in a group of pores. In the higher birds the shell is thinner and each canal opens in a single pore.

The dinosaur egg-shells already described by Dr. Van Straelen fall into three groups. In those associated with Protoceratops, from the base of the Upper Cretaceous, very small spheroids form a thin mamillar zone; the thick prismatic layer is traversed by relatively few air-canals, which end in minute pores and are of the same width throughout. In a Mongolian shell thought to belong to a duck-billed dinosaur the spheroids are larger, the pores a little larger, and the canals swell in the middle. In the shell from Provence the mamillar zone is much as in the last-mentioned; but above it are cavities which give rise to straight air-canals of equal bore, ending in pores of 0.1 mm. to 0.2 mm. diameter.

Thus the three types of supposed dinosaur eggs show a general agreement with one another. They differ from the eggs of all other creatures, but present certain resemblances to the eggs of crocodiles and birds, just as one would expect dinosaur eggs to do. We may therefore conclude that they really were laid by the dinosaurs the remains of which are found with them.

In addition to these three types, Dr. Van Straelen has in hand material from other parts of the world, including a probable dinosaur egg from the Oxford Clay of Peterborough and other eggs from the Oolite

of Great Britain. Now Mr. Roy Andrews tells us of one new type, of deinosaurian appearance, and another which is not so obviously deinosaurian.

The question whether all these eggs are those of dinosaurs has its converse: did all dinosaurs lay eggs? This cannot be taken for granted. The eggs of dinosaurs must have been hatched by the heat of the sun or of decaying vegetable matter, and it is natural to find them laid in rocks formed under desert conditions. To lay its eggs a dinosaur must have

trod on *terra firma*. The huge sauropods that lived in the estuaries of Wyoming, Argentina, and Tanganyika can in many cases have climbed on to the land only with great difficulty, and it is even doubtful whether their limbs could have supported their enormous weight out of the water. It may therefore well be that, like the water-inhabiting ichthyosaurs and sea-snakes, these monsters were viviparous. The East African Expedition of the British Museum is not likely to find their eggs in Tanganyika Territory.

Current Topics and Events.

IN the course of an interesting account of the discovery in the Gobi Desert of forty more dinosaur eggs, representing three species, given to the correspondent of the *Times* at Peking by Mr. Roy Chapman Andrews, the leader of the third expedition of the Natural History Museum of New York to Mongolia, which appeared in the issue of September 9, it is stated that implements of a type corresponding to the Azilian period of western Europe have been discovered by members of the expedition. These implements, made of red jasper, chalcedony, and chert, were found under the sand dunes which are characteristic of the district, and include such forms as spear- and arrow-heads, axes and knives, and so forth, of careful workmanship. Pieces of egg-shell of dinosaur and giant ostrich pierced with holes were evidently used for ornament. In a more recent deposit were two fossil skulls with other evidence of a later culture, which is stated to be "probably neolithic," although bronze points are mentioned as among the finds. Other relics of early man found in this area include a few implements of Mousterian type and pictographs illustrating moose, elk, and other extinct mammals of which the relation to the other finds is not specified.

It is obvious that this account of the discovery, apparently of primitive implements of human workmanship, must be received with all reserve until a further and more authoritative account is to hand, but it certainly holds out hopes of the fulfilment of the expectation that this expedition might well find traces of early man in Central Asia. The mention of implements of Mousterian type is of especial interest, coming as it does within a short time of the publication of the evidence for Mousterian man obtained by Fathers Licent and Teilhard de Chardin in Northern China and Mongolia, and the discovery of Mousterian implements associated with a skull of Neanderthal type in Palestine. It is stated that the earlier culture was separated from the later in stratification, but it is necessary that more should be known of the nature and character of the intervening deposits before it is possible to judge how far any wide separation in date is justified. The mention of bronze with the later culture may serve as a reminder that the contemporary use of metal and stone is of frequent occurrence. Stone implements from early sites in Mesopotamia have been known to be classified as Azilian-Tardenoisian until it was pointed out that their coexistence with copper had already been recorded. The geologists of the American expedition,

however, appear to be satisfied as to the antiquity of the early deposits, which they date at somewhere "between 10,000 and 20,000 years old." The further conclusion that primitive man came to Europe from Asia is here made to depend upon a dating of the Azilian culture in western Europe of 7000 years, which is quite possibly too low.

A PLASTER cast of the skull and jaws of *Protoceratops andrewsi* has been received from the American Museum of Natural History and placed on exhibition in the Fossil Reptile Gallery at the British Museum (Natural History). This is not the type, but one of the best skulls obtained in 1923, and is nearly full grown. It is 21 in long, 16½ in high, and 18½ in wide. The skull was found in the Djadochta Sandstone, a desert formation at the base of the Upper Cretaceous in the Gobi desert. *Protoceratops* is supposed to be the dinosaur that laid one kind of the famous eggs. It was herbivorous and one of the primitive Ceratopsia—a group of which *Triceratops* is the best-known example. It is not, however, regarded by the American palæontologists who have studied it as being in the direct line of ancestry of any of the American Upper Cretaceous genera, except perhaps *Leptoceratops*.

HOPES for the regeneration of China which were aroused by the prospect of liberating the funds accruing from the Boxer Indemnity seem likely to remain in abeyance for an indefinite period. The course of events at the moment is more than unfavourable to foreign intervention in domestic affairs, and in education, as in other matters, the Chinese, or at least the more aggressively demonstrative section of the population, do not hesitate to show their desire, and their confidence in their ability, to deal with the situation without outside assistance. In the meantime, the attitude of the students and the prominent part they are taking in the present disturbances lend support to the views of those with first-hand knowledge of the Chinese who are dubious of the advantages for China of an education on even partially Europeanised lines. It may be hoped, however, that this is but a passing phase which affects only the more restless and easily stirred section of the population. It must be remembered that in a country like China, in which, broadly speaking, scholarship has been the only passport to positions of authority, it was almost inevitable that the students would come to taking a hand in times of crisis, and equally inevitable that

here, as everywhere, they would tend to follow a subversive policy.

AN illuminating instance of the students' power in China, though only in what might appear a trivial matter, is given by Mr. Ellsworth Huntingdon, in *Scribner's Magazine* for September, in the course of an article in which he records the impressions of a recent visit to China. He states that the women of Fuchow have been compelled, at the order of the students, to abandon the three small swords it is customary for them to wear in their hair as a symbol of their right to defend themselves in case of need. Although Mr. Huntingdon's stay in the country was not prolonged, and it is notoriously unwise to form a judgment of the people except on something approaching intimate acquaintance, he has grasped certain essentials of the situation. There is conclusive evidence of the overwhelming desire of the Chinese man and woman for education up to the highest grade, but there are difficulties in the way in their desire for self-sufficiency. It is interesting to note that Mr. Huntingdon is in agreement with the view which holds that the use of the Boxer Indemnity money by the United States for educating Chinese outside China has not been an entire success in that it has led to the undue Americanisation of the student—a result disliked by the Chinese and not ultimately beneficial for the individual. The need for preserving what is best in Chinese culture, while allowing full scope to modern intellectual movements combined with high ideals of national welfare, has given rise to a suggested solution in a university which, combining several institutions under a common bond, might still allow free play to the aims and ideals of each of the constituent bodies. This suggestion, it may be noted, is not far removed from that which was put forward in these columns a few months ago in discussing the possibility of a scheme of co-operation between Great Britain and China.

THE decision of the Pharmaceutical Society of Great Britain to establish pharmacological laboratories for the testing of drugs to which the provisions of the Therapeutic Substances Act apply, namely, drugs the purity of which cannot adequately be tested by chemical means, has been advanced an important step by the announcement that applications are invited for the post of Director. The institution of the laboratories has been decided upon by the Council of the Society in order to afford opportunities for research in physiological methods of drug assay, to meet the demand for standardisation of therapeutic substances which will come from manufacturers, who for various reasons may not be prepared to undertake the standardisation contemplated by the new Act in their own laboratories, and also to afford opportunities for advanced students of pharmacy to receive training in the work. The Pharmaceutical Society has recently revised its examination regulations, and pharmaceutical students who have obtained the Society's qualification of pharmaceutical chemist, either directly or through the recently instituted

degree of Bachelor of Pharmacy of the University of London, will be able to take advantage of the opportunities for advanced work provided by the laboratories and should eventually be able to meet the demand for persons with knowledge of physiological standardisation which will follow from the operation of the new Act. The project has the complete approval of the medical authorities, and among the members of the committee which is advising the Council of the Society on the appointment of a Director and on the lines upon which the laboratory should be organised are Sir Humphry Rolleston, President of the Royal College of Physicians, representing the British Medical Association, Sir Nestor Tirard, representing the General Medical Council; and Dr H. H. Dale, representing the Medical Research Council. The Ministry of Health and the Medical Research Council have given the project their approval and support from the beginning, and it is felt that the laboratories will not only achieve their immediate objects in connexion with the Therapeutic Substances Act, but will also make important contributions to the advance of medical science.

THE Palæontologische Gesellschaft, an international society of palæontologists, will meet at Weimar in Thuringia on September 24-29, under the presidency of Prof. J. F. Pompeckj of Berlin. The organising secretary is Prof. Soergel of Tübingen, who also will lead several of the excursions. These include visits to travertine quarries near Ehringsdorf, where relics of Neanderthal man have been found; to old gravels of the River Ilm, with their vertebrate and cultural remains; to the Bunter sandstone of Berka, which shows worm-burrows and tracks of *Chirotherium*; and to the Muschelkalk of Jena, besides the museums in Weimar and Jena. Among papers announced are: Prof. O. Jaekel, "The Problem of the Skull, a Memorial to Goethe's Morphology"; Prof. Scheide-mantel, "The Monuments of Weimar", and Dr F. A. Bather, "Arenicoloides—a Suggestion," this last bearing on the worm-burrows of Berka.

At a recent meeting of the Aero Club of Norway, Lieut. R. Larsen outlined Captain R. Amundsen's plans for a polar flight next year. According to a report in the *Times*, Captain Amundsen has purchased from the Italian Navy a semi-rigid airship which was built in 1924 and has proved successful on several long flights. It has a cubic capacity of 670,000 cubic feet and a length of 328 feet. Three engines, each of 250 h.p., give it a maximum speed of 250 miles an hour. The crew will number sixteen, including Captain Amundsen and Signor Nobile, the constructor of the airship, who will act as navigating officer. At the beginning of 1926 the airship will fly from Rome to Pulham and thence, after overhauling, to Vernes, near Trondhjem, and if circumstances are favourable, direct to Spitsbergen. The final start will be made from King's Bay in April or May. The cruising radius of the airship is 3725 miles, and the voyage across the pole is 2235, which it is hoped will be completed in about fifty hours. Mooring masts are being erected at Vernes and at King's Bay.

DR ALEŠ HRDLIČKA, of the Smithsonian Institution, is expected to make a short stay in England towards the end of September on his return journey to the United States after visits to India, Australia, and South Africa. The object of Dr. Hrdlička's journey to these countries was to investigate on the spot the evidence bearing upon the problems of early types of man. While in South Africa he visited the famous Broken Hill Cave in which the remains of Rhodesian man were discovered, and in examining the deposits, was fortunate enough to discover further fragments of human skeletal remains. He proposes to exhibit these at a meeting of the Royal Anthropological Institute, and to submit to the fellows of the Institute the conclusions at which he has arrived from his examination of the deposits in the caves. Dr. Hrdlička's intention, appropriately enough, is to hand these bones to the British Museum (Natural History), where they will take their place with the remains of Rhodesian man.

THE twenty-fifth anniversary of the foundation of the Mond Nickel Works was celebrated on September 12 at Clydach, Glamorganshire, when Sir Alfred Mond, chairman of the Company, unveiled a bronze statue of his father, Dr. Ludwig Mond, F.R.S., who died on December 11, 1909. Dr. Ludwig Mond's name is connected more particularly with the manufacture of alkali and alkali products. In the late 'sixties of last century, he settled at Winnington in Cheshire, where, with the late Sir John Brunner, Bart., the firm of Brunner, Mond and Co. was built up for the manufacture of soda by the Solvay or ammonia-soda process. Much of the success which the firm achieved was due to the genius of Dr. Mond. The nickel works at Swansea arose out of the discovery, in collaboration with Langer and Quincke, of the group of compounds now known as the metallic carbonyls. This work in an abstract field of research was, with Dr. Mond's characteristic aptitude for seeing practical applications, quickly turned to account, and a process developed for the extraction of nickel from its ores. Dr. Mond will also be remembered as a most generous benefactor of science. The Davy-Faraday Laboratory at the Royal Institution and the International Catalogue of Scientific Literature are two specific examples of his munificence, though practically every movement in his day for the advance of physical or chemical science owed much to him and to his wise and inspiring counsel. Dr. Mond was elected a fellow of the Royal Society in 1891, and on the death of his widow in 1923, the Royal Society and the University of Heidelberg each became a legatee for the sum of 50,000*l.*, the income of which is to be employed for the endowment of research in natural science.

A COLD spell was experienced in England at the commencement of September. The mean maximum temperature for the first 10 days of the month at Greenwich Observatory was 62° 5 F., which is 7° 3 below the average for 65 years, 1841-1905, the mean minimum was 46° 9, which is 3° 9 below the normal. The mean temperature was 54° 7 and 5° 6 below the normal. In 1922, the mean tempera-

ture for September 1-10 at Greenwich was 55° 1; the mean maximum was 64° 0, slightly higher than this year, and the mean minimum was 46° 2, slightly lower than this year. In 1912, the mean temperature for the period was 54° 7, being in precise agreement with the present year; the mean maximum was 62°, slightly lower than this year, and the mean minimum 47° 4, slightly higher than this year. These are the only Septembers in the last twenty-five years having such cold days at the commencement of the month. On 6 days of the first 10 days of September of this year, the mean daily temperature was below 55°, and on September 9 and 10 the maximum thermometer failed to touch 60°. Frost occurred in situations open to the sky on 3 nights. The coldest day was September 5, with a mean temperature 51°, which is 10° below the normal. The maximum temperature in the 10 days at Greenwich was 68° on September 1. It is not exceptional for the shade temperature to register 80° during the period, and in 1911, at the end of the abnormal summer, the thermometer on September 7 and 8 exceeded 90° at Greenwich, and in the 10 days there were 5 days with a temperature above 80°. In 1906 the shade temperature on September 1, 2, and 3 exceeded 90°.

THE experiment in agrarian colonisation in the Tripolis initiated by the Italian Government in the year 1922 forms the introductory article of the *Revista della Tripolitania*, an official publication dealing with matters relating to the Colony, of which the first issue has recently appeared. The contents are not confined to official matters, and if the promise of the first number is maintained, it should prove a source of information of value for which systematic provision hitherto had scarcely been adequate in view of its importance, especially from the archaeological and historical point of view. In the present number there are several articles of interest to archaeologists, including an account of the city of Leptis as a centre for the production of oil in Roman times, a well-illustrated account of archaeological remains, and a description of an interesting mosaic from what apparently was a small votive shrine set up in the fields by a Roman citizen. Prof. A. Ghigi publishes the first instalment of a survey of Libyan fauna. The remainder of the first issue is composed of articles of practical interest to agriculturists, such as the cultivation of the olive, industries subsidiary to agriculture, the raising of cattle and goats in Libya, etc., and reviews of recent books dealing with the country.

A PROJECT due to M. P. Gaudillau is described in the *Comptes rendus* of the Paris Academy of Sciences of July 6, which will take advantage of the difference of level between the Mediterranean and the Dead Sea. It is proposed to construct a canal with locks from Haiffa up to a pass at the head of the valley of Esdremon, where a tunnel two or three kilometres long will connect with another short canal leading down a valley to the head of the pipe line; the

latter will carry the water to the Jordan valley, running straight down the steep mountain-side, the available head being 343 metres. From the power-house in the valley the outflow will be in a canal, running with a moderate slope along the side of the range, down to the Dead Sea, where an additional fall of 120 metres to a second power-house can be obtained. The Mediterranean water will be pumped from reach to reach of the canal by means of electric pumps. It is proposed to store the fresh water of the Jordan, and use it for irrigation, and as the present average flow of the river is about 70 m.³ per second, and this amount of water is now disposed of annually by evaporation, it is considered that, by raising the level and so increasing the surface of the Dead Sea, it should be possible to dispose of an influx of salt water of 103 m.³ per second. To raise this water 80 metres to the head of the pass will require 190,500 horse-power, and 617,000 horse-power will then be available for conversion into electric energy, 426,000 of which, or 240,000 kilowatts, will be available for distribution in Palestine and Syria.

THE inaugural meeting of the forty-fifth session of the Junior Institution of Engineers will be held at the Society of Arts on Friday, December 11, when Mr. J. S. Highfield will be inducted president of the Institution by Dr. Alexander Russell and will deliver his presidential address.

MR F. W. H. MIGEOD, the well-known African traveller and authority on native languages, has consented to assume the leadership of the British Museum East African Expedition in succession to Mr. W. E. Cutler, whose death from malaria was announced at the beginning of September. Mr. Migeod will sail for Dar-es-Salaam by the next boat.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned. Senior entomologist, Ministry of Agriculture, Egypt—H E. The Under-Secretary of State, Ministry of Agriculture, Cairo (November 1) Chemical officer in the Medical Research Laboratory, Nairobi—Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (October 15)

Our Astronomical Column.

RECENT MODIFICATIONS IN THE THEORY OF STELLAR EVOLUTION.—Prof. H. N. Russell, who shared with Prof. Hertzsprung the honour of originating the giant and dwarf theory of the evolution of stars, is contributing a series of papers to the *Scientific American* (beginning in the September issue) on the changes of view that have taken place in the last year or two.

Prof. Eddington showed from statistics that when absolute magnitude and mass were correlated, giants and dwarfs lay on a single curve, in contradiction to the earlier view that an abrupt change took place at the point where the star became too dense to act as a gas.

The recent spectroscopic demonstration of the immensely high density of the companion of Sirius was a striking verification of Eddington's conclusion that the atom when stripped of its outer electrons is capable of enormous compression without ceasing to be a gas. This completely modifies the older conception of the falling temperature in dwarf stars. It now appears that the temperature in their interiors will continue to rise far into the dwarf stage. But a full consideration of the best manner of modifying the theory in view of the new facts is postponed.

OBSCURING COSMIC CLOUDS.—Father Hagen, of the Vatican Observatory, has during recent years published successive lists of what he describes as dark nebulae, covering considerable regions of the sky, in both low and high galactic latitudes. Prof. Öpik, of Tartu Observatory, concluded from a count of the faint stars on the Paris Astrogaphic Charts that these were produced by some obscuring medium.

As this would be a matter of supreme importance in all researches on distant objects, Prof. Harlow Shapley has made a fresh investigation, by taking long-exposure photographs with 24-inch or 16-inch refractors. These show stars nearly 3 magnitudes fainter than the limit (14.5 mag) of the Paris Charts. His conclusion (Harvard Coll. Ob. Circ. 278) is that the deficiency of stars in the regions in question does not extend to these fainter stars, as it would if obscuring clouds were the cause of it. In other words, the actual distribution of the stars brighter than 14.5 is much more irregular than the laws of chance distribution would suggest. Doubtless this is a manifestation on

a larger scale of the well-known tendency of stars in many regions to group themselves along regular curves.

The "obscure nebulae" of Father Hagen are concluded to be an effect produced on the eye by the great contrast in star density between the neighbouring regions. The star deficiency is real, but the appearance of a visible obscuring medium is illusory.

U.S. NAVAL OBSERVATORY ECLIPSE OBSERVATIONS, 1905-18.—The appendix to the Publications of the United States Naval Observatory, Second Series, Volume 10, Part 2, contains an account of the total solar eclipses of August 30, 1905, and June 8, 1918, with aviators' notes on the total solar eclipse of September 10, 1923. The first account opens with the general report of the 1905 Expedition by Rear-Admiral Colby M. Chester, who was Commander-in-Chief of the special line squadron of three vessels detailed by the Navy Department. Three principal stations were occupied not far from the shores of the Mediterranean, and each station was completely equipped for photographing the corona with long and short focus cameras, for spectroscopic and polariscope work, for meteorological observations, and for position observations. At none of the stations was there any interference from clouds, and the programmes in general were carried out as planned. The volume contains the individual reports of all the officers in charge of the various departments, and covers 335 pages. It is well illustrated by a large number of excellent plates.

The reports of the 1918 eclipse, occupying 51 pages, are next dealt with. This eclipse was observed at Baker, Oregon, but partial cloudiness was responsible for the meagreness of the observations. Practically no spectroscopic results were secured.

Unfortunately the weather conditions for the eclipse of 1923 were also unfavourable at all points occupied by the naval aviators. The programme included photographs of the corona and the moon's shadow on the earth. Partly from the weather conditions and partly from the inherent difficulties of making such observations from aeroplanes, the photographs are stated to have no scientific value.

Research Items.

INTELLECTUAL GROUPING OF MEN.—In a "Study of the United States Senate" Mr Arthur MacDonald, of Washington, D C, raises the question whether it is possible to arrive at any general principles concerning organisations of men, comparable to those already elaborated about animal organisations. He thinks that all organisations of men, especially those of long standing, act according to laws most of which are at present unknown. As a preliminary investigation, he subjects the transactions of a Senate of three sessions to a statistical examination. He studies the attendances of members during each of the three sessions, the attendances of the various political parties, of business as against professional members, the frequency of remarks for each political party, the previous life and education of the senators and their success. From these data he draws certain tentative conclusions, the most interesting of which are, that the professional men average much higher in the frequency of their remarks than the business men; that the professional men are in the majority, and that a large proportion were reared in the country, that the Democrats excel the Republicans in university education, that more than half of the legislation initiated in the Senate receives little or no attention. The method is suggestive, and a comparison with other countries would be of great interest. It would, however, be advisable, when presenting material of this kind, if instead of giving averages only some indication of their reliability were also presented.

VANISHING INDIAN TRIBES.—The urgent necessity of recording Indian languages and grammar, as well as the traditions and folk-tales of N America, before it is too late, is well illustrated in the introductory remarks which precede the study of Wiyot grammar and texts by Gladys A Reichard which has just been published as Pt 1 of Vol 22 of the University of California Publications in American Archaeology and Ethnology. In 1850 the peoples speaking the Wiyot language probably numbered about 1000. In historic times they occupied a territory of about 465 square miles on the shores of Humboldt Bay and the lower reaches of the Mud and Eel rivers in north-west California. In 1910, at the time of the census, their numbers had fallen to 58 full-blooded Wiyot, 13 partly of Wiyot and partly of other Indian blood, and 81 partly Wiyot and partly white, making a total of 152. Further, there were only 11 full-blood Wiyot under twenty years of age. In 1922, when the present investigation was made, there were not more than 100 persons living as Wiyot, of whom very few knew the language. Some lived in two small settlements on Humboldt Bay, the others were distributed in groups of a few families in various townships. It is noteworthy that where a Wiyot marries a member of another tribe, whether Athapascan or Yurok, the children speak the language other than Wiyot. Seven individuals were employed in furnishing and checking the material. It was found that the difference in individual pronunciation was so great as to be almost dialectal, which makes it particularly regrettable that more extended sources of information could not be obtained. A sketch of Wiyot culture was given by Kroeber in his Californian Handbook published in 1911.

THE AMOEBA OF DYSENTERY.—There have been many claims in the past of the successful cultivation of *Endamoeba histolytica*, the parasite of amoebic dysentery, most, if not all, of which have proved erroneous. Some new research has recently been pub-

lished (Proc Nat. Acad. of Sciences, U S A. Vol. 11, No 5, 1925, pp. 235 and 239). Boeck and Drbohlav have now succeeded by the use of a special culture medium. This consists of slants in test-tubes of beaten-up whole egg coagulated in an inspissator. The slant is covered with Locke's solution containing 1 per cent of crystallised egg albumin (human serum may also be employed). Inoculated into this medium, the amoebæ grow and multiply, feeding on bacteria and blood-corpuscles if these are added, and persist for five days, but are most numerous at the end of 48 hours. By sub-culturing within this period the cultivated amoebæ have been carried on for more than 90 generations. They maintained their virulence, and the ninety-third sub-culture, five months from the original culture, produced dysentery when inoculated into kittens. Chiang has been able to transmit the *E. histolytica* of human origin to rats, and the infection of rats is readily transmitted from rat to rat by association in the same cage. The results of this investigation incriminate the rat as a possible carrier of the amoeba of human dysentery.

SPECIFIC IMMUNITY OF TISSUES.—*Science* for July 31 (No. 1596) contains an address by Prof Elliott Prentiss on "Specific Immunity of the Tissues and its bearing on Treatment". He points out that every species of animal and plant has special preferences of habitat and food. This applies even to micro-organisms parasitic in the human body, many of which are localised in certain tissues (see also NATURE, February 16, 1924, Vol. 113, p 242). Thus, in tuberculosis the tubercle bacilli rarely infect the muscular tissues. Experiments were performed by injecting tuberculous animals and individuals with emulsions of muscle, and a certain amount of benefit resulted, suggesting that the tissues resistant to a particular infection might be employed in the treatment of that infection.

INSULIN TREATMENT.—In *The Fight against Disease* (the organ of the Research Defence Society) for July, an account is given of the records of some forty cases of diabetes treated at one of the London hospitals with insulin. Three of the cases died—one from hæmorrhage after an operation, one from cancer and pneumonia, and one from coma. The remaining 37 cases have done well and have been discharged from hospital to resume ordinary life. Faith in the value of insulin is therefore absolutely justified. The article is illustrated with a striking plate showing the condition of a patient before and after insulin treatment.

SWEDISH RAINFALL.—In Part II. of the Årsbok for 1924 of the Swedish Meteorological Service are published the full figures of rainfall observations for the year. For each of the stations, which number about a thousand, beside the total fall for each month of the year, there are given the fall on the wettest day of the month, and the total number of days on which rain and snow fell. Each month is illustrated by a map, and there is a map of the year's rainfall. Comparison with previous years shows that 1924 was almost everywhere in Sweden an unusually wet year, the average excess being 16 per cent. Only in a few parts of the extreme south of the country was there a slight deficiency, which nowhere exceeded 10 per cent.

ECHO SOUNDING.—An important article on this subject appears in the *Hydrographic Review* for May 1925, the semi-annual publication of the International Hydrographic Bureau. The article is intended to

complete the information on this subject given in earlier issues of the *Review* (December 1923 and October 1924), and, while it contains little that is actually new, it collects certain scattered information from various sources in different countries. Descriptions are given of various forms of apparatus, including the sonic depth-finder of the American navy and Behm's apparatus, with a report of trials carried out with the latter by the Danish navy. The article concludes with a bibliography of the subject from 1912 to the present year. The contents of this article comprise Special Publication No. 4 of the Hydrographic Bureau.

TIDE PREDICTION—The annual report of the Tidal Institute of the University of Liverpool, just issued, describes the work of the Institute during 1924, the sixth year of its activity. On the more routine side, its work has included analyses of tidal observations made at Liverpool (4 years) and at Portland (1 year), the latter being done for the Admiralty; at Ystad, on the Baltic (4 years' observations), for the International Hydrographic Bureau at Monaco; and at Portage Island, Canada, for the Canadian Tidal Survey. Tidal predictions of the times and heights of high and low water during 1926 have been prepared for Liverpool, Portland, and seven ports in New Zealand and Australia; these predictions, made for or through the Admiralty, have been executed on the new machine presented to the Institute last year, and installed at the Bidston Observatory. The machine, which is of the Kelvin type, and made by Lord Kelvin's firm, is described and illustrated in the report, more harmonic constituents can be dealt with than by previous instruments of a similar kind, and various useful improvements are incorporated in the design. In addition to the development of methods of analysis and prediction, with special reference to this machine, various theoretical dynamical researches on tides have been published or continued during the year. The financial expenses of the Institute have been met partly by its earnings for commissions executed on behalf of other institutions, but mainly by the Liverpool Steamship Owners' Association.

WELSH SLATE—The Welsh slate-quarries, employing more than eight thousand men, produce the finest slates in the world, and furnish more than 80 per cent. of the total output in the British Isles. The National Museum of Wales has therefore done well to issue a small hand-book on "The Slates of Wales," written by Dr. F. J. North, Keeper of Geology in the Museum. It is a pamphlet of 66 pages, liberally illustrated, and presents an interesting subject in language intelligible to the general public. There is a general part, dealing with the nature and origin of slate and the manner in which it has acquired its peculiar fissile structure. The author might have brought out more clearly the fact that in the better-class slates practically the whole of the material has been reconstituted *in situ*, before and during the impression of the cleavage-structure. The more special part of the work includes an account of the distribution of workable slates in the Cambrian, Ordovician, and Silurian formations of Wales, some description of the getting of slate and the manner of preparing it for the market, and an interesting history of the Welsh slate industry, which dates from the latter part of the eighteenth century. There is also a good classified bibliography of the subject. This little book, published by the Museum at Cardiff at the price of sixpence, is admirably suited to engage the interest of the intelligent visitor, and to kindle a desire for fuller knowledge.

THE CONTINUOUS SPECTRUM OF HYDROGEN.—The continuous spectrum of gases is of great theoretical importance from the astrophysical point of view, as explaining the continuous spectra emitted by the sun and by stars. Messrs. H. Schuler and K. L. Wolf describe, in the *Zeitschrift für Physik*, July 18, a series of observations of the continuous spectrum of hydrogen, from which they conclude that it is due to the reunion of dissociated atoms to form molecules, and they express the opinion that this is also the case with other gases the molecules of which consist of more than one atom, including the halogens, for the continuous spectrum of which Steubing has recently given another explanation. Experiments show that the continuous spectrum of hydrogen, which reaches from about $4800 \text{ \AA}$ U to $2100 \text{ \AA}$ U, is not related in intensity to the Balmer series, or to the many line spectrum of the gas. The long wave-length boundary of the continuous spectrum agrees satisfactorily with that calculated from the heat of dissociation, which confirms the authors' view as to the origin of the spectrum. It is found that the intensity of the spectrum is strongly affected by the electric field, with which it increases, and it is suggested that reunion of atoms to form molecules is facilitated in an electric field. An experiment in which a very intense continuous hydrogen spectrum, with very few hydrogen lines, was produced in calcium vapour to which a little hydrogen was added, is considered to support the above view. Franck and Cario have shown that molecular hydrogen is dissociated by means of energy derived from excited mercury atoms, and it is thought probable that calcium atoms act in the same way, and that it is the reunion of these dissociated hydrogen atoms which causes the continuous spectrum in the last-mentioned experiment.

WATER IN CHEMICAL ACTION—A series of papers on the influence of water on certain chemical reactions, by L. B. Parsons, is published in the July issue of the *Journal of the American Chemical Society*. Solid potassium iodide and bromide both react immediately with moist chlorine, whereas no appreciable action occurs if the chlorine is dry. It is shown that a minimum partial pressure of water vapour, approximately equal to the vapour pressure of a saturated solution of the components present during the reaction, must be reached before reaction can take place. The reaction between hydrogen sulphide and iodine in ether solution runs to completion in the absence of water.

In the presence of water the reaction is incomplete:

The equilibrium point depends on the relative concentration of the water, diffused daylight has no appreciable effect. Atmospheric oxygen must be excluded from the system, however, as it oxidises ether to ether peroxide (Clover, 1922), thus changing the nature of the whole reaction. Many observations have been recorded of the ability of water to produce combination between various metals and iodine. It is now shown, however, that this property is not peculiar to water, but is possessed by many organic liquids. A close parallelism exists between the ability of a liquid to bring about reaction between a metal and iodine and the solubility of the metallic iodide in the liquid. Apparently the function of the liquid consists in removing the film of solid iodide from the metal surface. These researches are of importance in view of the large number of varied cases known in which water acts as a catalyst.

The Russian Academy of Sciences.

A MEETING was held at the London Central Y.M.C.A. on Thursday, September 10, in connexion with the bicentenary of the Russian Academy of Sciences, the celebration of which, at Leningrad and Moscow, has just been concluded. The meeting was arranged on the initiative of the Science Section of the Society for Cultural Relations (S.C.R.) between the peoples of the British Commonwealth and the Union of Socialist Soviet Republics (U.S.S.R.). Sir Richard Gregory, who occupied the chair, pointed out that the sole intention of the assembly was to send a message of appreciation and encouragement to scientific workers in Russia. For two centuries the torch of learning had been kept burning by the Academy of Sciences, and though at times it had flickered, it had never been extinguished since it was lit. One of the objects of the S.C.R. was "To take any action deemed desirable to forward the intellectual and technical progress of both peoples"; and the meeting could therefore appropriately associate itself with representatives of science who had gone to Russia to take official part in the celebration of the bicentenary of the Academy. Sir Richard Gregory referred appreciatively to Belopolsky's brilliant spectroscopic work at the Pulkova Observatory, and said that a forty-one inch object-glass was now being ground at the works of Sir Charles Parsons in Newcastle, for use in the largest refracting telescope in the world, to be erected in Russia.

Prof. A. N. Kriloff, a member of the Academy, gave some particulars of its establishment and early activities. He pointed out that two hundred years ago Russia differed very much from other European countries and was described as a purely Asiatic State. On the vast territory where now 150 millions have plenty of room to live, only eight millions were distributed. Almost all the inhabitants were illiterate, no schools existing except some in monasteries for the education of the clergy. Up to the time of Peter the Great, the only books were the Bible and books for church service, which were written in the old Slavonic language. When Peter the Great founded the Academy of Sciences, after having assisted at a meeting of the French Academy in Paris during one of his voyages, he invited the celebrated Leibnitz to prepare the statutes, and signed at the end of his reign an "ukase" promulgating the foundation of the Academy, but his death occurred before the work of the new institution began. Thus in a country with one single lay school created some twenty years before by Peter—the "Navigation School," which was managed by the Englishman Farquarson—an Academy of Sciences was established. It seems that such an enterprise had no sound basis, as not only "science" did not exist in the country, but the language had no actual word for it. The founders had the wisdom, however, to invite as the first members of the Academy not learned men and teachers of sciences only, but "creators" of the science, such as the two brothers Bernoulli and Euler. Euler was for fifty-seven years a member of the Russian Academy, and his far-reaching mathematical discoveries and works filled more than one half of the first hundred volumes of the proceedings of the Academy. During the first forty years of its existence, the Academy was not only a scientific body but also a school of education. The Russian members had to carry out research work in natural science and also to elaborate the Russian literary and scientific language, trying to approach the half Slavonic language

of the books to the spoken language of the people. The need to organise the language, and to establish a system, was so acute that some fifty years later a special Academy for Russian Language and Literature was created. This Academy had a special name—the Russian Academy—but in 1818 the new institution was joined to the Academy of Sciences to form one of its Sections, and the Academy of Sciences entered upon its second century with three sections, namely: (1) Physico-mathematics, (2) Russian Language and Literature, and (3) History and Philology.

"At the beginning of its second century," continued Prof. Kriloff, "we see the Academy to be a purely scientific institution of world renown, in a country with a definite system of education from primary schools to universities, with a well-developed literature, an elaborate scientific language, and scientists of Russian origin in different branches of sciences. The work of the Academy proceeds quietly like the work of analogous foreign institutions, and a great deal of it is devoted, as in the beginning, to the study of the vast territory of Russia and of its natural resources. In its third century the Academy enters at a time when the country and the people, having gone through a war and a revolution, have re-created the government and are re-creating life itself on a new foundation, but now the Academy stands on a solid ground and directs with certainty its researches and work to the benefit of the people and of the country. The Academy numbers forty-one fellows and has several scientific institutions under its direction, a library with four and a half millions of volumes, and an archive. In addition to biological institutions, other institutions are: the physico-mathematical one, with a new Röntgen-ray equipment, and the seismological survey. The mechanical works attached to this institution are able to supply instruments for international geophysical and geodetic research. At the chemical laboratory a new section of organic chemistry was created in 1923; and a Radiological Institute was organised in 1922. The well-known Pulkova Astronomical Observatory is extending its activity to the south of Russia and will begin observations with new first-class instruments supplied this year from England. Seven Museums belong to the Academy, namely: the Geological, Botanical, Zoological, the Pushkin House, the Historical and Bibliographical Museum, the Museum of Ethnology and Anthropology, and the Asiatic Museum."

Prof. P. I. Schmidt, curator of the Zoological Museum of the Russian Academy, gave an account of the organisation of regional survey work which has recently been instituted in the Republics. In the course of his address he said: Science is universal, and being the highest achievement of mankind, is its most valuable treasure. From this point of view, science is certainly international. But there is a kind of scientific research which is of special value for a definite country, such as the branches which study the nature of a country, its flora and fauna, the history and the life of its population. To rule a country and to guide it to prosperity and economic well-being, it is absolutely necessary to know the natural resources of the country, its geographical and climatological conditions, as well as the character and abilities of its population. Research of this kind is of a special value in Russia with its numerous regions differing widely in climate and population. During the past two centuries the

Academy of Sciences has played the first and chief part in the investigations of the natural resources of Russia and in the history and the study of the present conditions of its population. The small towns of Russia were never deficient in people interested in natural science, archæology, history, ethnography. These people steadily accumulated an extensive knowledge of the different regions they inhabited. Small societies, local museums, archives, biological stations have existed for some considerable time. But they could not before the Revolution unite their forces for the purpose of collaboration. Now, on the contrary, the separate organisations are freely able to get into touch with one another.

The first call for the organisation of regional survey came from the Academy in 1921, when an All Russian Congress of the Societies for Regional Survey was brought together in Moscow. In January 1922 a Central Bureau of Regional Survey was organised at the Academy of Sciences, Leningrad, with a branch in Moscow. This Bureau collected information about already existing institutions for regional survey, brought them into connexion with each other, and supplied them with every kind of help. The Bureau also started a periodical, *Regional Survey*, and published monographs and text-books on this subject. In March 1923, some 231 societies, their branches and associated clubs, were on the list, with 285 museums, 21 biological stations, and 16 natural reserves or parks. But a good many more societies have been started since, and up to last June the number of institutions dealing with regional survey was more than 1000. A map of Russia, on which these societies are marked, represents a dense conglomeration of points.

Many of the regional survey organisations have developed out of the former scientific societies, such as those in Vologda, Kostroma, Saratoff, Tamboff, and other cities. Those societies had already recorded observation after long periods, and at present they have only enlarged their programmes and increased their activities. A great many new societies of regional survey have also been created in small towns and villages.

Museums represent the simplest and easiest way for the popularisation of scientific knowledge, and are therefore largely used for educational purposes. But members of the societies do not restrict their work to such purposes. They do their best to do some scientific research as well. They organise meteorological and biological stations, and arrange excursions and scientific expeditions on a small scale in order to study the local conditions, ethnographical, statistical, and economic research is also undertaken by them. Many of the regional survey societies pay especial attention to the history and archæology of the country, they collect antiquities and study the history of the region. Most of the societies start the publication of the results in their own separate papers, and such periodicals are often of great value and interest. Some societies publish descriptions of their regions, for example, the regional survey society in a small town Usman, of the Voronej province, has published a map of this district on the scale of 4 kilometres to an inch, with a fairly good description of the Usman district.

The following resolution was then moved by Sir Arthur Smith Woodward: "That this meeting of members and friends of the Society for Cultural Relations between the Peoples of the British Commonwealth and the Union of Socialist Soviet Republics sends cordial greetings and congratulations to scientific workers in the U.S.S.R. on the celebration

of the bicentenary of the Russian Academy of Sciences, and in high appreciation of the great work by which the Academy has enriched the knowledge and culture of the world during the past two centuries, looks with confidence to the future for further contributions to promote the intellectual unity of mankind."

Sir Arthur Smith Woodward, in proposing the resolution, said he did so with special pleasure because he was an honorary member of the Russian Academy, and had profited much by the researches of some of the academicians and other Russian men of science. He had visited the seat of the Academy on three occasions under the old conditions in 1889, 1892, and 1903, and had learned to appreciate the facilities it afforded for scientific work. He made his home with Dr. Friedrich Schmidt, in whose rooms he met most of the active naturalists of St. Petersburg, as it was then termed. Dr. Schmidt himself was the leading authority on the rocks and fossils of the Silurian System, and was still more widely known by his investigation of the deposits in which the carcasses of the mammoth occurred in Siberia. Inostransev, professor of geology in the university, was busy with Russian stratigraphy and petrology, and trained several brilliant students. Lahusen, of the School of Mines, produced the first Russian text-book of palæontology on modern lines. Yakovlev and Tolmachev were also beginning their valuable researches on palæozoic geology. Baron von Toll was studying the collections he had made in the New Siberian Islands, where he eventually lost his life. In 1903 Salensky had just mounted the unique mammoth from Bereskovka in the Zoological Museum, and had completed the first memoir on it. Amalitzky was at work in Warsaw on the great collection of Permian reptiles which he had made on the Northern Dwina—one of the most important achievements in palæontology. Karpinsky was directing the Geological Survey of Russia, and publishing fundamental contributions to geology. He must be ranked among the foremost geologists of Europe, and, though now in his eightieth year, still retains all his enthusiasm as the honoured president of the Academy. Dr. Karpinsky is highly esteemed in England, and received the Wollaston Medal from the Geological Society of London in 1916.

Dr. T. R. Parsons, in seconding the resolution, referred to the physiological work of Pavlov and others which he had opportunities of seeing during a visit to Leningrad and Moscow a few months ago. The resolution was then put to the meeting and carried unanimously.

Cordial messages of support of the motion were received from the following among others: Prof. A. E. Boycott, Mr. Victor Branford, chairman of the Sociological Society, Sir Frank Dyson, Prof. A. S. Eddington, Prof. J. J. Findlay, Prof. J. W. Gregory, Prof. G. H. Hardy, Prof. L. T. Hobhouse, Prof. J. S. Huxley, Prof. J. N. Langley, Prof. A. D. Lindsay, Master of Balliol, Prof. C. J. Martin, Hon. Bertrand Russell, Prof. J. Y. Simpson, Prof. E. Soddy, Sir Gilbert Walker, Mr. H. G. Wells.

The Literature of Radioactivity.¹

THE report before us of the Committee on X-Rays and Radioactivity of the National Research Council of the United States consists of a review of radioactivity and its problems as discussed in recent

¹ Bulletin of the National Research Council. Vol. 10, Part 1, No. 51: Radioactivity. Report of Committee on X-Rays and Radioactivity, National Research Council. By A. F. Kovarik and L. W. McKeehan. Pp. 203. (Washington, D.C.: National Academy of Sciences, 1925) 2.25 dollars.

years. It is essentially a bibliography, not a developed account of the present state of knowledge in this subject.

The authors have taken as their starting point the year 1916, for in that year was published the well-known book of Meyer and von Schweidler, which contains an almost complete list of references to the earlier papers in radioactivity. The whole of the literature of radioactivity from that year until June 30, 1924, has been searched and the results recorded in this report. The limits of time have been overstepped in a few particular cases where earlier papers had been overlooked in previous works or where later papers were of special interest. Between the given limits the literature has been covered with remarkable thoroughness and very few, if any, papers have been missed. One result of this thoroughness is that many papers of doubtful interest or value are included, and that criticism and comment are reduced to a minimum. In general, the results and conclusions of an author are stated briefly and, unless the matter is of wide interest or of prime importance, comment is withheld.

The literature has been divided into seven main sections, under the following headings: the radioactive transformations, the α -, the β -, and the γ -rays, nuclear structure and radioactive processes, radioactivity in geology and cosmology, and the effects of the radiations upon matter. A concise account of each subject as it arises is given, and this is followed by reports on the papers published on the subject. A most valuable feature of the book is the collection of tables at the end of each chapter. In particular, we might mention the table of β -ray spectra and the table of γ -ray spectra deduced from β -ray spectra. One error must be pointed out. In the tables of p. 68 and p. 70, α -particles of range 3.8 cm are attributed to radium C, on the authority of Bates and Rogers. These α -particles have never been detected. Their presence is inferred from a knowledge of the transformations, and their range has been calculated from the period of radium C, using the Geiger-Nuttall relation.

A point which may give rise to some discussion is an attempt of the authors to introduce a systematised nomenclature of the radioactive substances. The symbol they propose consists of the atomic number of the element, followed first by the chemical symbol of the principal member of its series, and then by a Roman numeral indicating the genetic order of the radio-elements, for which the first two parts of the symbol are the same. Thus the proposed symbol for uranium 1 is 92 UI; uranium X₁ will be 90 UI, and uranium 2 will be 92 UII, and so on. This system is simple and rational, and has many and obvious advantages over the names and symbols in general use. But the latter, however arbitrary they may appear, were born out of the irregular and adventurous history of the subject of radioactivity and will not lightly be put aside for any system, rational though it be.

The report contains references to about 1500 papers, nearly all of which have been published in the brief space of eight and a half years, that is, at the rate of 15 per month. These figures show the need for a bibliography such as this, and also indicate the magnitude of the task undertaken by the authors. They are to be congratulated on carrying out their arduous and difficult work in a most thorough way. The result of their labours is a book which should save a great deal of time and trouble to workers in radioactivity.

J. C.

University and Educational Intelligence.

CAMBRIDGE.—The E. G. Fearnside Scholarship for research in the organic diseases of the nervous system has been awarded to Dr. T. K. MacLachlan, Pembroke College.

A STATISTICAL report on the universities of Canada for the year ended June 1924 has been published by the Dominion Bureau of Statistics. It gives a total of 18,026 regular students excluding those in preparatory (pre-matriculation) classes. Students of medicine numbered 2911, engineering and applied science 1949, theology 951, commerce 859, education 818, music 791, law 541, agriculture 526, household science 511. There was a very noticeable increase in the number of students pursuing "short courses," including courses organised in co-operation with the Workers' Educational Association, summer schools, and short courses in agriculture, journalism, "business," nursing, and other vocational subjects. Most of these courses were provided by the universities of Toronto, McGill, Manitoba, British Columbia, and Saskatchewan. 1862 students followed correspondence courses, provided chiefly by Queen's University, Ontario, and the universities of Toronto and Montreal. The current expenditure of all the universities amounted to nearly 1,800,000, the largest spenders being Toronto and McGill, nearly 400,000 each, Alberta 206,000, Saskatchewan 117,000, Manitoba 114,000, British Columbia 110,000, Queen's 100,000. The report directs attention to the fact that in some cases denominational universities (in the province of Quebec) are subsidised by the government. Of the total income rather less than one-fifth was in the form of fees, one-sixth was from investments, and one-half from government grants.

A SURVEY of engineering education in the land-grant colleges in the United States is given in Bulletin (1925) No. 5 of the Bureau of Education. The following important changes, among others, have taken place since 1910. Nearly all of the colleges have eliminated foreign languages from the curriculum or made them elective instead of compulsory. On the other hand, greater attention is given to English and to economics and business administration, required or elective courses being included to an increasing extent in such subjects as corporate organisation and finance, business law, patent law, accounting and cost keeping, banking, and salesmanship. Courses in highway and automobile engineering have been added to the curricula in many institutions. There has been a marked tendency towards postponing specialisation, the first year, or even the first two years, being made common to all branches, and more attention being given to thorough training in fundamental subjects. Much attention has been given to the orientation of freshmen. Shop practice instruction has changed in character, the general tendency being toward the conversion of the college shops into shop laboratories for illustrating modern methods of shop production, and of factory organisation and management, rather than for the acquisition of manual skill such as is required in mechanics. There has been some extension of the "sandwich" or co-operative system, especially in electrical and chemical engineering, under which the student spends half his time in the university and half in some industrial plant. In the United States this practice was first developed systematically by the University of Cincinnati.

Societies and Academies.

CAPE TOWN.

Royal Society of South Africa, July 15.—A. J. Hesse: Note on South African Rhyncophora. There are 270 species of the polymorphic genus *Brachycerus* in South Africa. Their chief enemies are secretary birds, bustards, and avicularid spiders. The eggs, which are rarely found, are deposited two or three at a time. Some larvæ are used as food by natives. Certain larval secretions form a native remedy for toothache. The adult insects are used by the Zulus as pendants for necklaces. Gradation of characters from species to species exists in certain groups.—F. G. Cawston: The molluscan hosts of South African Trematoda. Cercariæ have been isolated from at least eighteen species of fresh-water mollusca in South Africa, including the three genera of Ancyliidæ.—R. F. Lawrence: Note on the Arachnida of South-West Africa. The relation of the Pseudoscorpions to the other groups of Arachnida was touched upon and, in illustration, a new species of *Garypus* from Sesfontein, South-West Africa, was exhibited. This species is exceptionally large, measuring 7 mm in length, and is found under thin layers of weathering limestone. A new species of binocular spider, *Diploglena*, closely related to the genus *Nops*, which only occurs on the islands off the mainland of Brazil and Venezuela, is a striking example of the degeneration of the eyes owing to disuse in spiders living under stones.

PARIS.

Academy of Sciences, August 3.—Charles Nicolle and E. Conseil: The production of an experimental preventative serum for exanthematic typhus. Stages and solution of the problem. The serum obtainable from the ass, after experimental inoculation with the disease, has preventative properties, although the serum is not so rich in antibodies as the serum from human subjects recovering from the disease.—Maurice Fréchet: The law of errors of observation.—R. H. Gernay: The asymptotic solutions of the equations which define implicit functions, and on the asymptotic integrals of partial differential equations.—G. W. Ritchey: A new method of construction of large telescope mirrors.—V. Nechvile: Determination of the proper motions of stars from the 5th to the 16th magnitude, photographed on the first negatives of Henry.—Y. Rocard: The diffusion of light in fluids. A comparison of the formulæ obtained by Vessiot-King, Ramanathan, and Gans.—M. Auméras: The state of hydration of calcium oxalate. Under the conditions of the experiments described the salt had the composition $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$.—René Girard: The action of dilute solutions of acids on the ferrous metals.—V. Thomas: A new type of organo-magnesium compound. Starting with di-iodobenzene and magnesium, in addition to the formation of $\text{C}_6\text{H}_4\text{I MgI}$, there is evidence that some $\text{C}_6\text{H}_4(\text{MgI})_2$ is produced.—N. Arabu: Stratigraphic remarks on the fault of Ribeaupvillé (Haut-Rhin), to the north of Strengbach.—L. Jaloustre, G. Danne, M. Dementitroux, and A. Maubert: The radioactivity of the waters of Contrexéville (Vosges) the Pavilion and Quai springs. The water from the Pavilion spring contains 0.85 millimicrocurie of emanation and not exceeding 0.5 millimicrogram of radium per litre. The Quai spring contains 2.5 millimicrocuries of emanation and 0.33 millimicrogram of radium per litre.—Dedebant: The isolation of the dynamic tendencies in regions with a large daily variation of pressure.—Louis Emberger: The chondriome in plants.—Emile André and Franck Guichard: Contribution to the study of the fats from

American palms. Murumuru butter. Details of the usual physical and chemical constants are given for this fat, together with the results of methanolysis followed by fractional distillation of the methyl esters.—E. Ivanoff: A new mode of conservation and transmission of trypanosomes and spirochaetes in the larvæ of *Galleria melonella*. The larvæ of *G. melonella* can be utilised for assuring the continuity of cultures of trypanosomes in the laboratory, and for despatching them on a journey lasting several days.

WASHINGTON, D. C.

National Academy of Sciences (Proc. Vol. 11, No. 7, July).—Cornelia G. Benedict, Francis G. Benedict, and Eugene F. Du Bois: Human metabolism in an environment of heated air. Observations were made on five subjects (3 men and 2 women) placed in an air-tight bag through which a stream of heated, dry air (about 85°C) was passed. Loss of weight was 5 to 13 times greater than normal, oxygen consumption increased slightly, while skin temperature was fairly uniform and only one degree or so above normal owing to the cooling effect of perspiration.—Herbert M. Evans: Invariable occurrence of male sterility with dietaries lacking fat soluble vitamin E. Progressive loss of sexual powers and interest occurs in male rats, but it can be prevented by feeding, from date of weaning, single natural foods which cure the corresponding female sterility. Male sterility is often cured by protracted administration of vitamin E in ether extract of wheat germ.—Karl E. Mason: A histological study of sterility in the albino rat due to a dietary deficiency. Progressive stages of degeneration of the testes were obtained. Feeding with lettuce, provided some normal seminiferous tubules remain, checks degeneration, or, if fed before it sets in, prevents it.—Walter S. Adams: The relativity displacement of the spectral lines in the companion of Sirius (*v. NATURE*, August 22, p. 285).—W. M. Davis: The basin range problem. A recent visit to the Great Basin region, which includes all Nevada and parts of Utah, Arizona, California, and Oregon, provided examples confirming Gilbert's fault-block theory of the origin of many of the ranges.—James Kendall and Beverly L. Clarke: The separation of rare earths by the ionic migration method. An agar-agar gel containing a mixture of salts of two rare earth metals is placed in a wide tube between similar gels containing a faster cation (near the cathode) and a slower cation (near the anode). On electrolysis, the two boundaries remain sharply defined, but great care is needed in preparing the gels. The cations of the rare earth mixture should have different ionic mobilities leading to their accumulation at the ends of rare earth gel section. After runs of about twenty days with a current of 0.6-0.8 amp. at 240 volts, during which the rare earth section was moved up to 400 cm., separation of an yttrium-erbium mixture was effected (99.1 per cent. yttrium) and considerable separation of neodymium-praseodymium and gadolinium-samarium mixtures.—R. H. Fowler and E. A. Milne: A note on the principle of detailed balancing. The principle of entire equilibrium announced by Prof. G. N. Lewis has been exploited extensively in physics in recent years under the name (among others) of "the principle of detailed balancing."—W. H. Rodebush and E. F. Fiock: The measurement of the absolute charge on the earth's surface. Copper quadrants are mounted on insulators just above the ground and earthed through a ballistic galvanometer. Rotating quadrants directly earthed can be superimposed, making the former quadrants virtually the

inside of a conductor. The results indicate that the ground is negatively charged (10^{-10} coulombs per square metre); day and night (or solar eclipse) cause little change, but at the beginning of a rain-storm the charge drops to zero and may become slightly positive.—Edward W. Berry: Fossil plants from the tertiary of Patagonia and their significance. A collection from Mirhoja, Chubut Territory, contains determinable forms which are American and show no traces of African relationships. The age of the deposit is Miocene, and all except one specimen, a grass, are dicotyledonous arborescent forms or lianas. They indicate a genial climate with abundant rain for the period.—Laurence H. Snyder: Human blood groups and their bearing on racial relationships.—Carl Barus: Inductance treated acoustically by differential telephones.—Albert Björkeson: X-ray radiation from hot sparks. The X-rays originate chiefly at the solid electrodes.—Edwin H. Hall: The four transverse effects and their relations in certain metals. Knowing the electromagnetic coefficients (Hall and Ettingshausen effects) enables qualitative calculations to be made of the thermomagnetic coefficients (Nernst and Leduc effects).—Gilbert N. Lewis: The distribution of energy in thermal radiation and the law of entire equilibrium. Anticipations of this law have been less general than is now claimed. Its application to radiant energy is a crucial test. It leads to an equation of the form of the Wien distribution equation, which is contradicted by experiment. The Wien equation really applies to an "ideal" radiation analogous to an "ideal" gas.—Leonard B. Loeb: Ionic mobilities in ether as a function of pressure. As in permanent gases, the newly formed ions have about the same mobilities, but that of the positive ion decreases in about 0.03 sec., due apparently to a change in the diameter of the ion with age.—Richard C. Tolman: The principle of microscopic reversibility. Lewis's "law of entire equilibrium" has been stated before under the name of "the principle of microscopic reversibility." It is regarded as "an unproved assumption."—John P. Minton: The dynamical function of the tympanic membrane and its associated ossicles. Two modes of action are suggested: at low frequencies, the drum vibrates as a piston and the ossicles act as multiplying levers setting up relatively large pressure changes acting on the oval window; at high frequencies, they conduct flexural vibrations of the drum to the oval window. This explains middle-ear deafness to low frequency sounds and other effects.—Linus Pauling and Albert Björkeson: A new crystal for wave-length measurements of soft X-rays. The plane 00.1 of the hexagonal crystal β -alumina (Al_2O_3) gives very strong first and second order reflections. It has the unusually large grating constant of $11.2 \text{ \AA}$ and should be valuable for wave-length determinations with soft X-rays.—J. Hadamard: (1) On quasi-analytic functions. (2) The approximate evaluation of definite integrals. A better value is obtained by combining Simpson's value with the Euler-Maclaurin correcting terms.

The National Need of Scientific Research and Research Workers.

THE Prime Minister, in his speech to the House of Commons on June 29, expressed the view that, to find a way out of our present economic difficulties, one of the essential steps is "to link up science with our industries to-day." Lip service to this ideal can generally be obtained easily in most quarters, whether industrial, scientific, or political. It is when we come to discuss practical methods of realising the ideal that differences of opinion become most marked. The fundamental problem was admirably stated in the annual report of the Committee of the Privy Council for Scientific and Industrial Research for the year 1921-22 (Cmd. 1735):

"The problem before the country, as we see it, is to provide a means which will enable its population of nearly 50,000,000 to live and prosper. It is well recognised that for four-fifths of their food and for a great part of the necessary raw and semi-manufactured materials for industry, the people of these islands are dependent on supplies from overseas. These supplies can only be obtained if this country is able to carry on its exporting industries in future with greater efficiency than the rest of the world, for it is doubtful whether we can compete, either by lowering wages beyond the limits of our competitors, or by securing a much greater human effort than they. If these two avenues are closed, competition, in the end, is confined to greater efficiency resulting from scientific work, for, in the long run, our outstanding business skill and organisation could not make good a deficiency of production or an obvious inferiority in our goods. We consider that scientific and industrial research . . . is an essential factor in the national effort on which the continued maintenance of our present population unquestionably depends."

Two publications of recent issue have redirected attention to certain aspects of this problem. The Research and Inventions Committee of the British Science Guild (6 John St., Adelphi, W.C.2) has issued a report, published as a pamphlet, entitled "Scientific Research Workers and Industry." The National Union of Scientific Workers (25 Victoria St., S.W.1) has recently issued, under the title "On the Encouragement of Fundamental Research," a report of the Research Committee of that body, presented to and adopted by the Council. The two pamphlets are complementary, each to the other; the National Union of Scientific Workers confining itself to "fundamental" research of a purely theoretical nature, the British Science Guild being concerned with scientific research having a direct relation to industry.

The publication of the British Science Guild is an admirable document, from which it is easy to see that great pains have been taken to acquire a solid basis of facts, often in face of great difficulties and of the

reluctance or failure of those bodies having the knowledge of the facts to impart them. In a brief introduction and historical summary, it is pointed out that the Duke of Devonshire's Royal Commission on Scientific Instruction and the Advancement of Science set forth in its report, forty-five years ago, the paramount importance of scientific research, and urged the universities to assist in its promotion, stating that it was to the universities that the country must primarily look for its scientific workers. Neither the State nor the older universities, to which the appeal was made, took any serious steps to supplement the inadequate supply of scientific workers. The War opened the eyes of the country at large, and, since the War, developments in education and the establishment of the Department of Scientific and Industrial Research have already done much to foster scientific research and to bring about its better co-ordination with industry. "Undoubtedly," says the Committee, "the supply of scientific workers has been greatly augmented and the question now arises as to the use made of them in industry." It is to this question that the Committee directed its labours and with which its pamphlet deals.

Dealing with the supply of trained scientific research workers, the Committee of the British Science Guild, after an informative statistical statement of the data obtained by its inquiries, comes to the following conclusion: "It appears that Great Britain has now just about reached the pre-War standard of Germany and the United States, judged by the ratio of students to population, but there is no reason to suppose that the other two countries have remained stationary, consequently there is no justification for deciding that we have now raised our educational status to a position worthy of our place among the other nations, and that there is no need for further expansion." It is pointed out, however, that the universities are short of money and expansion in research facilities is consequently curtailed, despite the facts that the total income of the British universities has been more than doubled, while the annual Parliamentary grant is now nearly five times that of the pre-War period.

As to the utilisation of scientific research workers in industry, the chemical and engineering and allied industries probably employ most of the scientific research workers now engaged in industry. An attempt has been made to get scientific research domiciled in other industries by the establishment, under the ægis of the Department of Scientific and Industrial Research, of industrial research associations for a number of important industries. Very valuable work has been done already by these research associations, but, except in one or two instances, they do not appear to the Committee to be very extensively developed, the

number of scientific research workers employed by them being comparatively small.

The Committee of the British Science Guild says, however: "The success of the Associations, so far as they have been developed, justifies in our opinion the very fullest extension of their activities." The Committee makes several constructive suggestions to this end. In one of these suggestions it has already been anticipated in fact, namely, that the Government could offer considerable inducement to commercial firms to support research by permitting sums devoted to this purpose to be treated as trade expenses for the purpose of assessment for taxation. By an arrangement with the Department of Scientific and Industrial Research, the Inland Revenue does allow the *annual* subscriptions of industrial firms to research associations to be so treated as a trade expense, and, moreover, the income of the research associations so derived is not subject to income tax.

After pointing out "the vast gap there is, in many cases, between laboratory discovery and the commercial exploitation of a process," a gap often bridged only by years of skilled work, the Committee, in an Appendix, submits a memorandum on a proposed advisory committee on industrial inventions. This committee would consist of experts and would have the following functions:

(i) To examine the claims of inventions and to decide which are of probable industrial value.

(ii) To arrange for the semi-large scale, or complete commercial trial, of these inventions which are passed by the committee.

This is a valuable suggestion. The Conference of Research Associations, at its meeting in July last, discussed the same problem, how to bridge the gulf between laboratory discovery and the large-scale application of the discovery to industry. It is too big a question to be dealt with adequately here and now. In many cases, but not in all, it is mainly a question of financing the large-scale trials needed; and it has been suggested that, over and above the funds available to the research associations for research as generally understood, there should be some development fund out of which grants could be made for this specific purpose of shortening the "lag" between discovery and application.

The Committee of the British Science Guild directs attention also to the scheme adopted in the "A. D. Little" Laboratories in the United States, and suggests that a similar organisation "not in any way in competition with the existing Industrial Research Associations, but as a supplement to their activities," would perform a very useful function in Great Britain.

This publication of the British Science Guild is

certainly a most helpful and constructive contribution to the solution of the problem, how "to link up science with our industries to-day." That problem will not be near to solution, however, until our manufacturers generally come to regard scientific research as essential a part and parcel of industrial organisation as are, say, insurance, advertisement, and sales organisation.

We have but little space left to deal fully with the pamphlet issued by the National Union of Scientific Workers. Much of it, perhaps necessarily from the scope of the subject, is rather of the nature of moral exhortation than of concrete proposal, and it reads at times a little tritely. Nor are the authors always successful in "jining their flats." After declaring that the distinction between "pure" science and "applied" science, whether valid or not, is irrelevant to their purpose, they proceed to draw a vital distinction between "fundamental" research and "practical" research, as though this were not pretty much the same thing; and this distinction they base on what must generally be difficult, if not impossible, to determine, the "motives" which inspire the research workers. Who can say what these motives are? Some day perhaps we shall reach that happy state in which it will no longer be worth while to define "pure" and "applied," "fundamental" and "practical," as applied to scientific research. We shall be content to plead for thorough research, confident that if the research be thorough, the "pure" will look after the "applied," and the "practical" will not neglect the "fundamental."

Nevertheless, the National Union of Scientific Workers has performed a most useful service in directing attention to the paramount necessity, apart from any question of its practical application, of scientific research. It points out that the encouragement of research involves the arousing of a right attitude towards research among the general public and the provision of the right atmosphere for the research worker, and makes important suggestions as to financial provision for research.

Birth-Control: Individual and Social Ethics.

The Ethics of Birth-Control (Report of the Special Committee of the National Council of Public Morals.) Pp xvi+179 (London. Macmillan and Co., Ltd., 1925.) 2s. 6d. net.

THIS is a curious publication. The spirit in which the Committee approached its task may be judged from the introductory remarks of the chairman, the Bishop of Winchester. In these he says that many people regret the public discussion now given to such

topics as birth-control, and that "in large measure the Committee share that regret."

It is this attitude which is in itself a serious matter. Here is an invention—the mechanical and chemical control of conception—which is one of the few important biological inventions made in historical times. The discovery of anæsthetics and that of various methods of killing or weakening the action of harmful bacteria are the only others that are in the same street with it. It points a practical way to a final satisfactory control by man of his own evolution, since the only other regulators of numbers which are not merely pious wishes are war, pestilence, famine, or overcrowding. Yet a serious body of public men regret, decades after its widespread adoption in practice, that it should be *discussed*.

Many biologists and students of medicine remember the nausea which rewarded their first dissection or their first post-mortem. It is a natural and almost instinctive reaction, and yet it is their duty and their privilege to be able to overcome it and so devote themselves to the search for truth or the relief of suffering. The cases are precisely parallel.

The net result of the Committee's deliberations is that its members continue to sit on the fence. They find that the use of contraceptives may in special medical or even economic circumstances be advisable, but that self-restraint should always be the ideal. One paragraph in especial deserves quoting as a dogmatic statement which to many will seem simply at variance with fact, and at any rate begs the question. "The use of contraceptives is a symptom of the artificial character of our civilisation whereby for large numbers of people a simple healthy normal married life is difficult and in some cases all but impossible." Even from this very moderate condonation of birth-control, a minority, including Canon Lyttelton, dissent. They say that the use of contraceptives is *never* to be condoned, and give as their chief reason that it is unnatural ("a frustration of God's design in Nature").

It would be very interesting to know which of the activities of civilised man the minority would call natural. When I used to meet Canon Lyttelton regularly—when I was under him in Sixth Form at Eton—he (*inter alia*) taught us Latin, Greek, and Divinity, and did his best to stop beagling in the school. Now I would quite respectfully submit that these activities are no more natural—or unnatural—than the practice of birth-control; and one of them—the antipathy to chasing wild animals—though I sympathise with it personally, yet is in direct opposition to one of the most ingrained "natural" propensities of humanity.

No: to damn a practice because unnatural is logically, to revert to a senseless Rousseauism. From

one point of view civilisation is all unnatural. From another it is all natural, since it all springs from the nature of man: and as a matter of fact, the qualities in it which are usually regarded as more natural are just those which we share with the brutes, not those peculiar to our human dignity, and more often than not need repression instead of encouragement. It is meaningless to judge the practices of civilised man on this basis: they may justly be appraised as right or wrong, or as useful or harmful—but natural or unnatural, no.

Turning to the majority report, we find another defect which is characteristic, unfortunately, of too many idealists, both within and without the Church. They consider what they would like to see in existence, while partly or wholly neglecting what is in existence; and they run to extremes. It is pretty obvious that we should prefer to see more self-control in marital relations rather than more self-indulgence. But they do not seem to have reflected that such self-control as they recommend is not and certainly will not be for centuries "practical politics" for the mass of the human race. Among the distinguished people who gave evidence we find medical men, philosophers, social workers, clergymen, and others: one figure is conspicuously absent, and that is "l'homme moyen sensuel"—the type of the mass for which the Committee aspires to proscribe. For at least half the population for generations to come, the alternative to contraceptive methods is not self-control but the reverse, with as a result excessive child-bearing, with consequent misery, ill-health, poverty and degradation of standards.

Further, if there is one thing that is clear, it is that contraception has come to stay. Sir William Beveridge has made it fairly clear that to no other cause than the improvement of contraceptive methods can the marked drop in the birth-rate which started some fifty years ago be ascribed; for the suggestion of Brownlee that we are dealing with some undefined phenomenon of race-fertility cannot be entertained without much more cogent evidence.

Then our Committee runs to extremes. It may be true, as we said, that *more* marital self-control would be a good thing; but that does not in the least imply, as an elementary acquaintance with logic will convince, that *complete* self-control, save for the deliberate purpose of producing children, is the ideal. It is undoubtedly true that more self-control in the matter of eating would be a good thing, both morally and physically, for the nation; but that does not make complete abstention from food the ideal. A more real parallel is between the two aspects of eating and the two aspects of marital relations. We must eat to live,

but we can also enjoy our food for its own sake. So we must practise marital relations to reproduce our species; but we can also find in them a means, as the Quakers put it, of "mutual endearment," or, in the more flaming words of Blake, make of it "that . . . on which the soul unfolds her wing." If we are to refrain from all intercourse save that intended for procreation, we must logically disapprove of all devices, such as good cooking, designed to promote enjoyment of food, instead only of gluttony.

Finally there remains the biological aspect. The drop in the birth-rate has been differential. That of all classes used to be the same: in the last half-century or so the birth-rate of the professional and upper classes has fallen much more than that of the rest of the population. Although this is not such a dysgenic matter as is sometimes made out, since some very good stock, such as those of miners and agricultural labourers, show little drop in fertility, yet it *is* dysgenic: the proportion of desirables is decreasing, of undesirables increasing. The situation must be got in hand. But it is impossible to persuade the classes which have adopted contraceptive methods to drop them by idealistic appeals to self-control. The way to begin to stop the rot is to diffuse these practices equally through all strata of society. Then and only then can we draw breath and look round for more constructive eugenic remedies. But, meanwhile, as Mr. Wells in his letter in NATURE of July 25 suggests, we have no cause to be complacent about our intellectual and social freedom as compared with Tennessee, in the matter of birth-control we are doing a similar thing; we are preventing servants of the State from giving information on a vital topic, largely because of the attitude of certain religious bodies to the topic. Not only thus, but while thus preventing the giving of the information where it is most needed, we take not the slightest steps to prevent it being given in a thoroughly unpleasant way, on a commercial basis—to those who can pay for it.

I make no apology for dealing with the subject at such length. We have here one of the most urgent matters of applied science with which our civilisation has been called upon to deal. Let us not bungle it as we bungled the whole human and social side of the application of science to industry at the time of the industrial revolution. I would recommend the separate report signed by Dr. Bond alone of the Committee as embodying a very cautious but a very sane attitude.

This booklet is interesting for much of the evidence which it contains; it is also interesting as showing that the Churches are alive to the existence of the problem. But we must regret that the report on the whole allows the question to fall to the ground between, on the one

hand, the stool of "natural" repugnances which ought to have been long ago overcome, and the stool of over-idealism on the other. When all is said and done, there is very little guidance here of a practical or social sort. The "ethics" of the book's title are chiefly individual ethics; the social ethics of the question are less fully and less broadly discussed. The over-concern of the individual for the salvation of his own soul was a characteristic of the Middle Ages. It springs up when there seems to be no prospect of reconciling the organisation of society with religious and moral ideals. To-day we do not feel that as an impossibility—however hard the task obviously will be, we see society as more plastic. We must be very careful not to allow the individual's concern about his own soul to loom so large as to stand in the way of social improvement or to block the social view. It would be an interesting task to try to discover how far the acknowledged lack of grip of the Church on the nation to-day comes from the retention of this spirit, which, however necessary a product of medieval times, is out of place in a society the leading minds of which are upheld by the consciousness that man through knowledge may acquire conscious control of evolution. But that is another story!

J. S. HUXLEY.

Mining and Metallurgy in the British Empire.

Empire Mining and Metallurgical Congress, held in London, June 3-6, 1924. Proceedings Part 1: General Section of Congress. Edited by the General Secretaries and G. F. Bird and Percy Strzelecki. Pp. xv + 474 + 14 plates. Part 2: Mining (Section A of Congress.) Edited by the General Secretaries and G. F. Bird and Percy Strzelecki. Pp. xvi + 542 + 25 plates. Part 3. Petroleum. (Section B of Congress.) Edited by the General Secretaries and Dr. A. E. Dunstan. Pp. xvi + 239 + 21 plates. Part 4: Metallurgy of Iron and Steel. (Section C of Congress.) Edited by the General Secretaries and L. P. Sidney. Pp. xiv + 296 + 14 plates. Part 5: Non-ferrous Metallurgy. (Section D of Congress.) Edited by the General Secretaries and G. Shaw Scott. Pp. xii + 137. (London: Empire Mining and Metallurgical Congress, 225 City Road, 1925.) Parts 1, 3, 4, 5, 10s. 6d. each; Part 2, 21s.; Set of 5 vols., 42s.

THE records of the proceedings of the first Empire Congress of Mining and Metallurgy have now been published in five substantial volumes, which will be found to contain much of interest to every one engaged in any branch of the numerous industries included under the headings mentioned in the titles of the volumes. It must not, however, be supposed that the

importance to the British Empire of last year's Congress can be in any way properly gauged by the printed record of its proceedings. The real value of this Congress is to be found rather in its personal touch, in the essential fact that this was the first occasion upon which the men engaged in developing the mineral resources of the British Empire met together in conference, made each other's personal acquaintance and were able to discuss, both formally and informally, the numerous perplexing problems which they are called upon to solve in their daily routine. It may safely be said that the most valuable work that was done at the Congress was the work that will never be published, the heart-to-heart exchange of views for which it afforded so many opportunities, and to which the formal papers, which now lie before us in their permanent form, were so often looked upon mainly in the light of more or less unwelcome interruptions.

The importance of the subject-matters of this Congress can scarcely be overestimated, including as they do the employment in the service of mankind of the mineral wealth of our vast Empire; let it be remembered that the utilisation of the earth's mineral resources embodies human civilisation. The savage can live and does live on the organic products of the earth; but the dawn of civilisation only arose when man began to avail himself of the earth's inorganic products also, and every advance in civilisation and in the amenities of life depends upon the fuller and better use made of mineral resources. The work of mining and metallurgical technologists consists in discovering how to use these resources to the best advantage and how to supply them in the vast quantities and at the comparatively reasonable cost which the complexities of our modern existence imperatively demand. It is for this purpose mainly that the technologist calls upon science to come to his aid, and, as the records before us abundantly show, the application of scientific principles is playing an increasingly important part in helping the development of the mineral resources which Nature has placed at the disposal of mankind; never was there a time when the need for the employment of scientific methods was more urgent, for it would almost appear as though this were the only direction in which it is possible to seek for a remedy against the prevailing creed of work-shyness from which the Empire and Great Britain, in particular, are to-day suffering.

Whatever science and technology may effect, the basal fact remains, that we must necessarily look to labour to carry out the methods which the trained mining engineer and metallurgist may devise. In his recent presidential address to the Iron and Steel Institute, Sir Frederick Mills showed that the cost of production of all ordinary commodities includes from 90 to 95 per

cent. labour cost, and this high figure emphasises strikingly the fact that it is labour alone which, in the ultimate resort, determines whether the articles which modern civilisation demands shall or shall not be supplied at a reasonable cost. This point was admirably put quite recently in another presidential address, that of Sir Thomas Holland to the Institution of Mining and Metallurgy, and his words are worth quoting :

"As civilisation, such as we know it, depends absolutely on our being able to rely on supplies of the base metals, each improvement in the treatment of ore adds enormously to the actuarial value of civilised life. On the other hand, every increase in the cost of mining and metallurgical operations renders inaccessible correspondingly our available reserves. As labour is the most important item in our working costs, a trades' union meeting can undo in a morning the results of a generation's research work in ore-dressing and metallurgy."

It is considerations such as these which serve to show the Empire Congress of Mining and Metallurgy in its true light as a bulwark of civilisation, based on the co-operation of those engaged in furnishing humanity with those materials which it has learnt to regard as indispensable to its present comfort and future progress. Towards the attainment of this object, the free interchange of ideas between all English-speaking mining engineers and metallurgists (for it must not be overlooked that, in spite of the title of the Congress, American technologists were good enough to take part in it and to share in the deliberations of their British fellow-workers, to the great delight of the latter) is perhaps the most effective means that could have been devised.

To turn to the published proceedings, it has already been indicated that they form the least important part of the real work of the Congress, in spite of the fact that they contain much information of the greatest use to students of technology. There are five volumes, the first dealing with general subjects, and the four others devoted respectively to mining (coal and metalliferous), petroleum, iron and steel, and the non-ferrous metals. The first volume contains a certain amount of what may be considered as ephemeral matter, records of proceedings, speeches at the Guildhall banquet, etc.; but together with these there are three general papers of very great importance, namely, general reviews of mining and metallurgical practice in three great sections of the British Empire—Canada, Australasia, and South Africa—each of which contains a wealth of information concerning the development of their respective mineral resources which could only have been brought together on such a unique occasion as this Congress presented. Perhaps it may be regretted that the Canadian paper

deals somewhat too exclusively with the mining side of the question and that the great metallurgical developments in Canada are not adequately represented.

The mining papers contained in the second volume, with but few exceptions, deal with the broad general problems of mining, such as should properly be considered at an Empire Congress, where detailed discussions of any one particular district are perhaps somewhat out of place. A number of these papers are devoted to a review of general economic conditions, applicable to mining generally, and cover the broad field which more particularly interests such a Congress, whilst it is a highly significant fact that fully half of the papers are devoted to the all-important considerations of the safety, health, and wellbeing of the men engaged in mining operations. It is surely a good sign that although Britain holds to-day the proud position of conducting its mining operations with a higher standard of safety than any other country in the world, we are not content with having reached this stage, but are striving onwards towards a still greater measure of security for the underground worker.

The volume on petroleum may fairly be regarded as one of the best of the series, each paper dealing with one or other aspects of the subject, the economics, the geology, the methods of exploitation, the after-treatment and the storage and transport of the products being each one fully considered, so that this volume presents a complete epitome of the petroleum industry as it exists in the world to-day. It may fairly be asserted that papers such as the above, showing the stage which the development of an industry has attained, are not only the most suitable for presentation to a Congress but also likely to prove of the greatest permanent value to the future student of the subject.

The volume devoted to iron and steel is necessarily less homogeneous than the last named, because the great complexity and numerous ramifications of this vast industry prevent any similar general treatment of the subject as a whole. There are, however, a number of broad papers which deal particularly with the various principal branches, such as a review of coke manufacture, of fuel economy in general, of blast-furnace practice, of the production of various special steels, and of the economics of the iron and steel industry, whilst two papers describing the progress of the industry in Canada and in India respectively are of very special importance.

The last volume, dealing with the non-ferrous metals, is perhaps the weakest from the point of view of an Empire Congress, but this again is due in a measure to the fact that it is called upon to cover so wide a range. It falls to the lot of but few men to acquire a satisfactory working knowledge of more than one of the many

metals included in the non-ferrous group, and hence the presentation of general papers becomes a problem of extreme difficulty. Several of the papers, such as that of Dr. Rosenhain and Mr. Archbutt on the alloys of aluminium, form important contributions to our knowledge of one particular metal, but would perhaps be better suited to the pages of the Journal of the Institute of Metals than to the records of an Imperial Congress, where breadth of vision is of more importance than microscopic accuracy of detail.

It would not be right to conclude this notice without some reference to a matter which, although it occupies but an insignificant place in these volumes, being comprised within two pages of letterpress, will possibly prove to be the most important outcome of the Congress, namely, the foundation of an Empire Council of Mining and Metallurgical Institutions. This Council proposes to act as the organ of co-ordination and co-operation between all these institutions throughout our wide-flung Empire, and, it is hoped, will form a common bond between all British mining engineers and metallurgists. It should enable them more effectively to pool their knowledge and experience and to foster the already existing feelings of true comradeships between them. In this way it should advance still further the development of our Imperial mineral resources, thus playing an important part in strengthening and maintaining the British Empire.

HENRY LOUIS.

The God of Aristotle.

Aristotle's Metaphysics. A Revised Text, with Introduction and Commentary, by Prof. W. D. Ross. Vol 1, pp. clxvi + 366. Vol. 2, pp. iv + 528. (Oxford: Clarendon Press; London: Oxford University Press, 1924.) 2 vols. 48s. net.

IN preparing this new edition of Aristotle's *Metaphysics*, Prof. Ross has performed an arduous and a valuable service. From many points of view the *Metaphysics* may be regarded as the hardest nut which Prof. Ross has in the course of his great undertaking yet had to crack, and it is doubtful whether any of the works of Aristotle which have still to appear will present equal difficulty. In the first place, the text is incredibly corrupt. The earliest MS. we possess is separated from Aristotle by a distance of twelve centuries, some of the books which are included are clearly intended to form part not of this but of a different work, other books necessary to the argument are missing, while there is acute controversy over the correct order of the books we have. Finally, Aristotle's writing bears, even more clearly than in his other works, evidence of being, not a mature treatise, but a series of notes for lectures or jottings

preliminary to the preparation of such a treatise, the consequence being that, partly owing to the clipped and allusive character of Aristotle's remarks, partly owing to the gaps caused by the mutilation of the text, the amount of matter that has to be supplied by conjectural emendation is exceptionally large.

The *Metaphysics* is exceptional, too, in the amount of controversy it has aroused; for the argument—and this is the second great difficulty with which Prof. Ross has had to contend—if of unusual difficulty even for Aristotle, full of contradictions, repetitions, definitions which are neither used nor kept, preliminary statements which have no sequels, and divisions of subject-matter which are elaborately made only to be cut across by later and incompatible divisions. The consequence is that when you have to use what Aristotle did say as a basis on which to conjecture what he may have said, while many guesses are plausible few can be more than guesses; so that different commentators have been able to indulge themselves even more freely than usual in their old trick of seeing in disputed passages confirmation for their own particular views.

Through all this tangle of controversy and conjecture Prof. Ross keeps a clear head. He is sane in suggestion, sensible in judgment; he never advances a view without giving good reasons for it and for the rejection of contrary views, and he displays a knowledge and writes with an authority which fully entitle his edition to be ranked among the nobler works of scholarship. Most valuable is a clear and full statement of the probable views of Socrates and Plato as disclosed by references in Aristotle, of the metaphysical views of Aristotle himself, and of his highly peculiar theology.

I say views advisedly, and not system, for of all works on *Metaphysics*, Aristotle's is surely the most tentative and empirical. There is no statement of general principles, no ordered advance from agreed premises, but tentative suggestions, fresh starts and reduction of common-sense views to more precise terms. As Prof. Ross puts it, the *Metaphysics* "expresses not a dogmatic system but the adventures of a mind in its search for truth."

It is matter for surprise that these adventures have attained their enormous celebrity. Taken in the broad, Aristotle's speculations, especially with regard to the profounder truths, unlike those of Plato which give pleasure even when they do not carry conviction, are neither intellectually convincing nor æsthetically satisfying. They owe much of the veneration with which they have been regarded to their somewhat arbitrary selection by the early Catholic Church as a basis for its theology. Aristotle was the first to bring into philosophy the conception of "the prime mover" as the ultimate principle of the universe, a prime mover

who was spirit and not matter, and stood at the head of a hierarchy of spiritual essences. This conception seems to have been enough for the Christian fathers. Yet it is surprising that they should have embraced it so readily. Aristotle's cosmology is one of great clumsiness; he announces six different kinds of being as the constituents of his universe, the prime mover, intelligencies actuated by love of him fifty-five in number, the soul of the first heaven, the souls of the fifty-five spheres, the first heaven, and the fifty-five spheres, and he makes no effort to resolve this somewhat grotesque plurality. Furthermore, Aristotle's prime mover was not the creator of the universe, since matter is eternal, nor is he a personal God feeling interests outside his own concerns, nor is he a God of love, since to entertain emotion would be to interrupt contemplation. Contemplation is, indeed, the one pursuit of the prime mover, the objects upon which his intellect is directed being geometrical problems.

In this, and indeed in other respects, Aristotle's prime mover is more like the ancients in the last play of the "Back to Methuselah" Pentateuch than the God of any known religion. They, too, are engaged in the study of mathematics; their creator shares Aristotle's distrust of emotion and his respect for intellectual activity as the end and purpose of existence

C. E. M. JOAD

Our Bookshelf.

Allen's Commercial Organic Analysis. Vol. 3. Hydrocarbons, Bitumens, Naphthalene and its Derivatives, Anthracene and its Associates, Phenols, Aromatic Acids, Gallic Acid and its Allies, Phthalic Acid and the Phthaleins, Modern Explosives. Fifth edition, revised and in part rewritten. Edited by Samuel S. Sadtler, Dr. Elbert C. Lathrop, and C. Ainsworth Mitchell. Pp. ix + 732 (London: J. and A. Churchill, 1925.) 30s. net.

THIS new volume, while showing many changes in the personnel of the contributors, and some increase in size, very closely follows the ground covered by the corresponding volume in the previous edition published fifteen years ago. The only definite change would appear to be the separation of the text on benzol with its derivatives from bitumens, so that it may be included later with dye-intermediates. With the extra space available, many of the more recent developments in analytical chemistry have received consideration. The newer indicators for hydrogen-ion control and the comparative testing of antiseptics, to mention but two subjects, have received special attention.

In spite of the fact that a large number of slips appear to have escaped the proof-reader, especially among the chemical formulæ (e.g. copper sulphate, p. 150, trinitroresorcinol, p. 337, and cellulose trinitrate, p. 598), the very high standard of the fourth edition has been maintained and all the sections have been brought up-to-date.

In the examination of tars, pitches and oils, American standard methods have been followed. A good account is given of the testing of natural gas in the bitumens section, but in the detailed description of the Orsat-Burrell apparatus the figure appears to have been omitted. The fact that the testing of salicylic acid is given thirty pages and saccharin twenty pages, to take only two examples, gives some idea of the thoroughness with which this standard work is compiled. The explosives section has been doubled in size since the last edition. A big portion of the increase, however, is due to the inclusion of long extracts from the First Report of the Home Office Departmental Committee on the Heat Test (1914). The curious diagrams of this report, with dimensions inserted on simple apparatus to the third and fourth decimal point, are also reproduced. The reference to Silberrad Ablett and Merryman (p. 613) for the estimation of nitroglycerin in cordite, although similarly given in some other text-books, is incorrect; it should read Silberrad, Phillips, and Merri-man. The poor reproduction of Will's apparatus (p. 704) makes the lettered description in the text of little value. It is incorrect to dry tetryl by heating above its melting point (p. 641) before determining this constant. Reference is made in the explosives section to the new gelatinisers and stabilisers, such as diethyldiphenylurea and unsymmetrical diphenylurea, which were largely used in Germany during the War in the manufacture of propellants. No method of testing these products is given, as it is stated that no method has hitherto been published. J. REILLY.

Pathologische Pflanzenanatomie. In ihren Grundzügen dargestellt von Prof. Dr. Ernst Kuster. Dritte, neu bearbeitete Auflage. Pp. xii + 558 (Jena: Gustav Fischer, 1925.) 24 gold marks.

THE field of pathological plant anatomy is a difficult one to define, and the author has interpreted it in a broad sense. This book, which now appears in a third and enlarged edition, fills much the same place in relation to pathological plant anatomy that Haberlandt's well-known work does to the "physiological anatomy" of normal plant tissues and organs. It is an abundant source of carefully sifted information on the anatomy of pathological growths in their multiform variety. Numerous clear illustrations add greatly to the value of the work.

The special part opens with an account of variegation, which occupies about 40 pages and deals with much of the modern literature of the subject from an anatomical point of view. The second chapter is devoted to etiolation, the effects of the absence particularly of the short rays of the spectrum. Not only the well-known effects on chromatophores and stems are considered, but also the effects of darkness on hair formation, pollen, endodermis, algæ, and fungi. Three other chapters are devoted respectively to intumescences and similar structures involving increase of water content, wound-tissues and regeneration; and galls. The last two topics occupy 160 pages and include a consideration of callus, tyloses, wound cork, and gum formation.

The general part is arranged in three sections dealing with the histogenesis, the developmental mechanics and the "ecology" of pathological tissues, making up the greater part of the book. Here the facts are regarded

from a more philosophical viewpoint. Such general problems as senescence in plants, inhibitions to development, polarity, abnormal cell divisions, cell fusions and necrosis are considered on the basis of definite facts. The examples cited include anything from "involution" forms of bacteria to abnormal reduction divisions and the splitting of tissues by frost. As regards the *Entwicklungsmechanik* of pathological tissues, the causes discussed are classified as mechanical, osmotic, chemical, radiant energy and correlation. Under the latter head brief reference is made to gigantism and polyploidy, while Haberlandt's theory of wound hormones also receives consideration.

The final section deals "ecologically" with such topics as the healing of wounds, formation of aerenchyma and hydathodes, and with functional adaptation of tissues. The book is a most useful reference work for botanical laboratories, for one frequently finds the facts of pathological histogenesis considered from an unstereotyped point of view.

R. R. GATES.

Practical Chemistry by Micro-Methods. By Prof. Egerton Charles Grey. Pp. ix + 124. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1925.) 4s. 6d. net.

FORTY years have now elapsed since the appearance of Haushofer's "Microscopic Reactions," and the science of qualitative microchemical analysis, of which it was the sign and portent, seems to have remained indigenous to Central Europe. Behren's "Introduction to Microchemical Analysis," the first edition of which was published in 1899, has become almost a classic, and the text-books of Schoorl and Emich have also achieved a well-earned reputation. Prof. Grey's elementary introduction to microchemical work is, we believe, the first English book to deal with this subject, and in extending a welcome to it, we hope that it will be the means of spreading the use of the microscope in chemical work.

Microchemical reactions are for the most part more decisive than the ordinary microscopic tests; they necessitate greater cleanliness and entail greater economy in time and material. Notwithstanding these facts, we cannot agree with the author that microchemical analysis should be substituted for ordinary analysis in our schools and colleges, though we grant that, at the appropriate stage, nearly every student would gain from such a course as he prescribes. It is a trite criticism that many secondary schools attempt work which is much better left to the university; here is a subject which pupils in their last school year could pursue with great advantage, and with this manual in hand they could work with very little supervision from the teacher. The low price of the book is also a recommendation, and prompts the question if it heralds a new dawn of cheap—and good—printing and publication.

Elements of Physical Biology. By Dr. Alfred J. Lotka. Pp. xxx + 460. (Baltimore, Md.: Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1925.) 25s. net.

For a long time methods analogous to those of statistical mechanics have been applied to animal and plant communities. But just as in physical chemistry these methods soon become intolerably cumbrous and may generally be replaced by thermodynamical calculations which ignore the individual molecule, so in the book

before us the author has applied to biological problems a treatment of the type familiar in chemical statics and kinetics. These methods are applied to the growth of populations, whether of bacteria, insects, men, or railway engines, and to relationships between different species, for example, between a parasite and one or more hosts. The author has the problem of evolution always before him, and considers analytically the effect on population of a change in the behaviour of individuals.

It must not be supposed, however, that the book is a mere formulation of theories. It contains a vast amount of facts unattainable within the same compass elsewhere. For example, the account of the circulations of hydrogen, carbon, nitrogen, and phosphorus in Nature is the most satisfactory known to the reviewer, and accounts are given of the experimental work of Pearl and his pupils on animal populations, and the statistical results of Willis and Yule on "age and area." No biologist conversant with mathematics can possibly read this book without coming upon many ideas which will be new to him, and many mathematicians will find in it applications and problems of a refreshing novelty.

The Folklore of Fairy-Tale. By Macleod Yearsley. Pp. xiii + 240. (London: Watts and Co., 1924.) 7s. 6d. net.

In his brief preface, Mr. Yearsley modestly denies himself any claim to originality. His object is to bring together in a concise and popular form the salient points in the science of fairy-tales. He confines himself, where possible, to those tales which are current in the British Isles or have been introduced and popularised by British writers. His material, therefore, is largely drawn from Grimm and Perrault. In discussing the scarcity of the indigenous *marchen* type in Britain, he follows Hartland in attributing its suppression to the influence of Evangelical Protestantism. On this point he might have enlarged to the advantage of his readers. Hartland's suggestion indicates an important contributory cause, but it by no means entirely explains the facts. Why, for example, do British *marchen*, with one or two exceptions, survive especially in the areas in which revivalism usually flourishes? Mr. Yearsley illustrates his argument throughout with numerous examples and parallels. As many of the sources from which he draws his material are out of print or too technical for the ordinary reader, his book adequately serves the purpose for which it is intended.

An Elementary Chemistry. By E. J. Holmyard. Pp. viii + 424. (London: Edward Arnold and Co., 1925.) 5s.

MR. HOLMYARD's book covers the syllabuses for the various First School Certificate and the London Matriculation Examinations. It is brightly written with a modern outlook, and should appeal to young students. Questions for exercise and useful "Revision Notes" (at the end of the book) are provided. Interesting historical notices, some portraits of famous chemists, and reproductions of manuscripts and pages of famous books enliven the text, and the whole treatment may be commended. The author has evidently appreciated the common difficulties and mistakes of young students, so that his experience may also be of assistance to teachers.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.*]

The Taungs Skull.

IN NATURE of July 4, 1925, p. 11, Sir Arthur Keith has attempted to show first that I called the Taungs skull a "missing link," and secondly, that it is not a "missing link."

As a matter of fact, although I undoubtedly regard the description as an adequate one, I have not used the term "missing link." On the other hand, Sir Arthur Keith in an article entitled "The New Missing Link" in the *British Medical Journal* (February 14, 1925) pointed out that "it is not only a missing link but a very complete and important one." After stating his views so definitely in February, it seems strange that, in July, he should state that "this claim is preposterous."

Despite this reversal of opinion, Sir Arthur tells us that the skull "does show human-like traits in the refinement of its jaws and face which is not met with in young gorillas and chimpanzees at a corresponding age." He appears to have overlooked the fact that in addition to these and other facts brought forward by myself, the temporal bone, sutures, and deciduous and permanent teeth (according to Dr. Robert Broom) also show human-like traits. Moreover, as Prof. Sollas has so ably shown, the whole profile of the skull is entirely different from that in living anthropoids, thus indirectly confirming my discovery that the brain inside the skull-dome which caused this profound difference was very different from the brains inside the skulls of modern apes.

The fact that Sir Arthur was unable to find the *parallel sulcus* depression in the replica cast sent to Wembley illustrates how unsatisfactory the study of the replica can be in the absence of the original.

With reference to the question of endocranial volume, I would state with Prof. Sollas that this "is a matter of only secondary importance." Nothing could exemplify this matter better than the condition of affairs in the Boskop race, where the endocranial volume was in the vicinity of 1950 c.c. (The average European's endocranial volume is 1400-1500 c.c.) Indeed, the world's record in human endocranial volume (2000 c.c.) was discovered in a "boskopoid" skull by Prof. Drennan in a dissecting room subject at Capetown this year. It is well known that the elephant and the whale have brains much larger than those of human beings, but no one has inferred from that that their intelligence is greater. It is fairly certain that size of brain has some relation to size of body, as Dubois has shown. It is highly probable that the australopithecoid man-apes were relatively small as compared with the gorilla. It is not the quantity so much as the quality of the brain that is significant.

Sir Arthur is harrowed unduly lest the skull may be Pleistocene. It is significant in this connexion that Dr. Broom, who first directed attention to this possibility (of which I was aware before my original paper was sent away), regarded it nevertheless as "the forerunner of such a type as Eoanthropus." It should not need explanation that the Taungs infant, being an infant, was ancestral to nothing, but the family that he typified are the nearest to the pre-human ancestral type that we have.

In view of these facts, there is little justification

for the attempted witticism that in making the "African ancestors typified by the Taungs infant" the "foundation stone of the human family tree"—whatever that may be—I am making "a mistake identical with that of claiming a Sussex peasant as the ancestor of William the Conqueror." This is merely a case of mistaken identity on the part of Sir Arthur. I have but translated into everyday English the genealogical table suggested by Dr. Robert Broom (NATURE, April 18, 1925), with which I agree almost entirely. I take it, however, as a mark of his personal favour that Sir Arthur should have attacked my utterance and spared Dr. Broom's.

Sir Arthur need have no qualms lest his remarks detract from the importance of the Taungs discovery—criticism generally enhances rather than detracts. Three decades ago Huxley refused to accept Pithecanthropus as a link. To-day Sir Arthur Keith regards Pithecanthropus as the only known link. There is no record that Huxley first accepted it, then retracted it, but history sometimes repeats itself.

RAYMOND A. DART.

University of the Witwatersrand,
Johannesburg

PROF. DART is under a misapprehension in supposing that I have in any way or at any time altered my opinion regarding the fossil ape discovered at Taungs. From the description and illustrations given by him (NATURE, Feb. 7, 1925, p. 195) the conclusion was forced on me that *Australopithecus* was a member of "the same group or sub-family as the chimpanzee and gorilla" (NATURE, Feb. 14, 1925, p. 234). In the same issue of NATURE, Prof. G. Elliot Smith expressed a similar opinion, describing *Australopithecus* as "an unmistakable anthropoid ape that seems to be much on the same grade of development as the gorilla and chimpanzee without being identical with either."

All the information which has come home since Prof. Dart made his original announcement in NATURE has gone to support the close affinity of the Taungs ape to the gorilla and to the chimpanzee—it is a member of that group. Prof. Bolk, of Amsterdam, and Prof. Wingate Todd, of Cleveland, Ohio, have directed attention to the fact that the skulls of occasional gorillas show the same kind of narrowing and lengthening as has been observed in that of the Taungs ape. Prof. Arthur Robinson has shown that there is a wide variation in the size of jaws of young chimpanzees of approximately the same age, the smaller of the jaws approaching in size and shape to the development seen in the Taungs ape. The dimensions of the erupting first permanent molar of the Taungs ape and the form of its cusps point to the same conclusion—that *Australopithecus* must be classified with the chimpanzee and gorilla. It is, therefore, "preposterous" that Prof. Dart should propose to create "a new family of *Homo-simiadæ* for the reception of the group of individuals which it (*Australopithecus*) represents." It is preposterous because the group to which this fossil ape belongs has been known and named since the time of Sir Richard Owen.

The position which Prof. Dart assigns to the Taungs ape in the genealogical tree of man and ape has no foundation in fact. A large diagram in the exhibition in Wembley, prepared by Prof. Dart, informs visitors that the Taungs ape represents the ancestor of all forms of mankind, ancient and modern. Before making such a claim one would have expected that due inquiry would first be made as to whether or not the geological evidence can justify such a claim. From his letter one infers that Prof. Dart does not set much store

by geological evidence. Yet it has been customary, and I think necessary, to take the time element into account in constructing pedigrees of every kind. Dr. Robert Broom and, later, Prof. Dart's colleague, Prof. R. B. Young, have reviewed the evidence relating to the geological antiquity of the Taungs fossil skull, and on data supplied by them one can be certain that early and true forms of men were already in existence before the ape's skull described by Prof. Dart was entombed in a cave at Taungs. To make a claim for the Taungs ape as a human ancestor is therefore "preposterous."

Finally, Prof. Dart reminds me that whales and elephants have massive brains and that many large-headed men and women show no outstanding mental ability. Still the fact remains that every human being whose brain fails to reach 850 grams in weight has been found to be an idiot. Size as well as convoluted pattern of brain have to be taken into account in fixing the position of every fossil type of being that has any claim to be in the line of human evolution—the Taungs brain cast at Wembley possesses no feature which lifts it above an anthropoid status.

ARTHUR KEITH

Royal College of Surgeons of England,
Lincoln's Inn Fields,
London, W.C., September 5.

The Rate of Man's Evolution.

ALL those interested in the important question of man's evolution will have read with pleasure Sir Arthur Keith's recent contribution to this problem in *NATURE* (August 29, 1925). It is with some diffidence, therefore, I record the fact that I am unable to agree with certain of his conclusions. He states in the article above mentioned (p. 317), that the Ice Age terminated "some 12,000 years ago," and again (p. 319), that the well-known palæolithic epoch—the Mousterian—"closed some 20,000 years B.C." It is, however, known that the close of palæolithic times coincided with that of the Ice Age, and thus, according to Sir Arthur Keith's dating, the distinct and widespread civilisations of the Aurignacian, Solutrean, and the Magdalenian, together with the change of climate and of fauna that accompanied them, can have occupied no more than 10,000 years.

Again (p. 319) your readers are informed that "the Chellean phase of culture was moving towards its zenith 100,000 years ago." But, in view of the fact that there is good reason to believe the Chellean phase is referable to the Cromer Forest Bed, and that two major glaciations, with their interglacial periods, have occurred since the Forest Bed was laid down, it is, I think, perhaps unwise to assign any implements of Chellean age to an epoch so comparatively recent as 100,000 years from the present.

To suppose these things is surely to exceed the archaeological and the geological speed limits?

The recent discovery, in a cave in Galilee, of portions of a human skull of Neanderthal type has a direct bearing upon the matter under discussion in this note. In Mr. Turville Petre's account of this find (*Times*, August 14, 1925) he states that the specimens were found in an undisturbed deposit containing flint implements, which "seem to indicate a transition culture from Early Palæolithic, or Acheulean, to Middle Palæolithic, or Mousterian." If this determination is correct, then it is clear that the skull fragments must be referred to the *beginning* of the Mousterian period. Yet Sir Arthur Keith claims, for some unreported reason, that the Galilee individual lived about 20,000 years B.C., which, accord-

ing to his own dating, is when the Mousterian period ended.

As for the antiquity of the modern type of man, I am compelled to conclude, after a review of all the evidence, that the discovery of human bones of this type in ancient deposits at Galley Hill and elsewhere support definitely the reality of this antiquity.

J. REID MOIR.

One House, Ipswich.

The Cause of Surface Tension.

IN an article in *NATURE* for April 4 (vol. 115, p. 512) Mr. N. K. Adam revives the old question as to the reality of a state of tension in the surface film of a liquid, and expresses grave doubts as to its existence. I myself fell into this same heresy in my first flush of enthusiasm over Laplace's theory of capillarity; what eventually led me back into the fold was the contemplation of simple cases like the following.

Consider a drop of water hanging in equilibrium below a hole in the bottom of a vessel of water, and for definiteness let us mean by the "drop" the water below some horizontal plane P drawn very close to the bottom of the vessel. The drop is acted on by two downward forces, its weight, and a net downward push exerted by the water above, for there can be no doubt whatever that over the plane P the hydrostatic pressure exceeds atmospheric.

Now the crucial question is, what upward force balances these two downward forces? It is no good arguing about resultant inward forces on the surface particles of the bottom part of the drop, for not even a water-drop can lift itself by its own boot-straps. Some portion of matter outside the drop must be pulling or pushing upward upon it. The only matter that can be doing this is the contiguous water above the drop. But cohesion by the central part of this water cannot be the cause, for the *net* force exerted by the central part, due to kinetic or contact pressure minus cohesion, constitutes the force of hydrostatic pressure referred to above, and certainly acts downward. We are inevitably driven to the conclusion that the surface skin of the adjacent water above P is, on the whole, pulling upward upon the surface skin of the drop.

This is all that we mean when we say that the surface skin is in a state of tension, any selected portion of the skin pulls harder than it pushes upon each adjacent portion. Note that the maintenance of the equilibrium of a surface molecule is quite a different matter; that depends upon the sum of all pulls and pushes taken together, and has no bearing on the question of the relation between pull and push in a given direction.

This argument is very elementary and old, of course. But I cannot find where any one has pointed out how simply the tension can be deduced also from those same Laplacian conceptions which have proved so misleading to many.

Let us in thought divide the surface skin by a perpendicular plane R , and let us consider a horizontal slab of the liquid of unit width, of thickness dx , and extending perpendicularly from R to a point on the right beyond the molecular range of action, h . The liquid to the left of R will attract this slab with a component of force normal to R equal, say, to tdx ; and it will also press upon the slab with a force pdx where p = intrinsic pressure, which we assume to be equal in all directions at a given point in consequence of the fluidity (We omit the superposed action of the hydrostatic pressure.) Then in the interior

$p=t$, whereas at the surface $p=0$, while t has here just half of its value in the interior, representing the attraction of half of a hemisphere upon the slab. We may therefore conclude that in the surface skin on the average $t > p$, and the skin to the left of R will exert a net pull upon the skin to the right equal per unit length to

$$T = \int_0^h (t-p) dx.$$

T is the "surface tension."

This argument involves no assumption of any special mechanism or arrangement of molecules on the surface; such an arrangement, different from the state of the interior, may exist, as a separate phenomenon, or it may not. The argument does, however, lose most of its meaning if one adopts the modern idea that h is really very short, perhaps less than a molecular diameter. The difficulty is not to conceive how the state of tension can exist, but to show from molecular behaviour that it *must* exist. The surface must be a kinetic affair, with large momentary fluctuations of form and of molecular concentration, so that tension and pressure become mere statistical averages. Perhaps nothing more is possible for the theorist than to fall back on physical instead of molecular considerations, and to conclude from these that the dance of the surface molecules is so ordered as to make the mean horizontal tension exceed the mean pressure.

E. H. KENNARD.

Cornell University,
Ithaca, New York.

THE water drop hanging below an orifice takes up such a shape that the relation between the pressure difference p inside and outside the surface, the potential energy per unit area of the surface γ , and the radii of curvature of the surface R_1 and R_2 , is

$$p = \gamma \left(\frac{1}{R_1} + \frac{1}{R_2} \right).$$

This relation is deduced simply from the fact of potential energy in the surface proportional to its area, and holds good whatever the law of force or mechanism by which this potential energy is produced (See, for example, Besant and Ramsey, "Hydrostatics," 6th ed., p. 192; Gibbs, "Equilibrium of Heterogeneous Substances," Works, vol. 1, p. 228.) It is sufficient to account for the equilibrium of the drop. The fluidity of the water allows it to attain the configuration of least potential energy very rapidly, and this will be such that the curvature at each horizontal section is exactly that necessary to give an internal pressure at the level of that section, equal to atmospheric pressure plus the pressure due to the column of water above that section. Greater curvature will be necessary at the bottom of the drop than at the top. In my article in NATURE of April 4, I suggested that the greater internal pressure under a convex surface of liquid might be pictured as due to the convergence of the normals to the surface, drawn inwards, the attractive forces on molecules in the surface act along these normals. These inward forces are the cause of potential energy in the surface, since work must be done to form a new surface by dragging molecules from the interior. Since the relation between curvature and internal pressure can be deduced independently of the mechanism causing the surface potential energy, it is evident that the inward attractive forces on the surface molecules

can set up the pressure distribution within the drop which is consistent with minimum potential energy. No more is required to account for the equilibrium of the drop.

I think Dr Kennard is mistaken in his treatment of the statics of the problem. The molecules of water are moving across the plane P continually, so that any attempt to regard the drop merely as a piece of inert heavy baggage, which leads to the conclusion that it cannot be held up by cohesion in the centre, is not clear enough to give a solution. It does not help, when meeting the difficulties arising from this point of view, to ascribe the support of the drop to a hypothetical surface skin, about the properties of which nothing is stated. The consideration of the pressures at different levels in the drop at once gives the solution, as it so often does in hydrostatical problems. The motion of the particles of the drop, including exchange between surface and interior, is so rapid that it is not possible to ascribe the supporting of the weight of the drop to any particular region, and the method of pressures appears the only one available.

Dr Kennard's expression for the "tension" deduced from Laplace's theory seems quite sound as an expression for the average deficiency in internal pressure in the surface layer. But I can see no reason for calling this a tension. It might be properly termed a state of rarefaction. A rather similar argument was, I think, employed by Worthington (*Phil Mag*, 1884—I am without means of verifying the reference), who considered that there was probably a deficiency in density near the surface, and therefore there must be a tension in the surface to separate the molecules. Such arguments as these seem to be inspired more by the desire to employ the word "tension," with as many as possible of its associations, in connexion with the surface, than by any clear picture of what really is the structure in the surface.

There are other reasons than Laplace's theory for not regarding the surface as containing any material structure like a contractile skin. I have found three of these particularly convincing. Following Langmuir, in the attempt to unravel the structure of thin surface films, I found that it led nowhere to speculate how the fatty acid molecules acted on the surface skin so as to diminish its "strength." But regarding the molecules of the fatty acid film simply as hard floating objects, attracted by the water perpendicularly to the surface, attracting each other laterally, and small enough to show Brownian movement, very complete analogies have been drawn between these films and matter in three dimensions; and the shapes of the molecules have been shown to be exactly what would be expected from their structural formulæ, obtained by the methods of organic chemistry. It would be scarcely possible to find a stronger *a posteriori* argument against the existence of a contractile skin than this success obtained by its total abandonment.

Osborne Reynolds found that the motion of oil spreading on a dust-covered surface of water suggests strongly that the oil is spreading by reason of an inherent expansive force, and does not resemble at all that to be expected if the oil were being pulled out by the tension of a skin on the water. He was considerably puzzled by this, as he felt bound to consider the expansion of the oil as due to the tension of the water surface (Works, vol. 1, p. 410, Brit. Assoc. Rep., 1881).

Maxwell (Works, vol. 2, p. 553; "Ency. Brit." art. on Capillarity) considered what would occur if the surface tension between two liquids became

negative, concluding that in this case we should expect the interface to extend itself spontaneously, by folding and puckering. He pointed out that liquids do actually mix by diffusion, which is molecular motion. Some such puckering of the interface seems to be a necessary consequence of a "contractile skin" becoming negative in tension and becoming an expanding skin. No genuine case of mixing of liquids in this manner seems to be known; with Mr. Jessop I have recently examined what was reported as a case, but found it due to a peculiar combination of gravity and diffusion, only possible in very special circumstances, and not connected with capillary phenomena (Proc. Roy. Soc. A, 108, 324).

Regarded solely as a convenient mathematical equivalent for the potential energy associated with unit area of the surface, the term surface tension avoids constant reference to the principle of virtual work, and shortens calculations, but as a means of gaining insight into the molecular structure of surfaces, there is evidence that it has proved very misleading.

The Miller Effect and Relativity.

It is reasonable that the unexpected results of the recent repetition of the Michelson experiment by Prof. D. C. Miller should have made Dr Silberstein say that they "knock out the relativity theory radically" (NATURE, May 23, p. 798). But though Einstein has built the special Theory of Relativity on the negative result of the experiment, I am of opinion that the Miller effect does not prove anything against the general theory. It should be stated emphatically that the *special Theory of Relativity can only be built up rigorously if based upon the general theory*, not inversely. The special theory does not consider any but linear transformations. But avoiding every acceleration implies the impossibility of comparing measures and clocks moving relatively to each other. On the other hand, the usual supposition that the effect of a passage from rest to uniform motion, etc., tends to zero with the time in which it takes place, can only be based upon the assumption that the ratio of the time to the proper time (interval) between two points on any (curved) world line remains finite and different from zero. But this assumption requires the consideration of non-linear transformations, and thus of the general Theory of Relativity.

In order to put the so-called "Principle of Equivalence" into a slightly different form, we make the following statements:

1. The world can be considered as a set of points which represent "event-particles."
2. The points can be ordered along "world lines" by means of a "relation of identity," which is given by the psychical phenomenon of recognition.
3. A bundle of world lines can be considered as a single world line. This is based upon the psychical judgement that they "belong together." This "relation of whole and parts" ("relation of class") permits us to consider the set of world points as four-dimensional.
4. There are considered binary relations between different points, namely, "relations of cause and effect," which can be represented by the "lines of causality."

5. *It is possible to describe every physical phenomenon by using only the relations of coincidence, identity, class and causality.*

These assumptions imply that we can construct a four-dimensional "graph" of universal history, graphs topologically equivalent not being distinguished by this definition. The very meaning of the ether-question is: Do the phenomena require a particular *metrical* system to which the universe must be referred? The reduction of the question to this form enables us to answer it at once, and obviously in the negative. For a topological transformation never can translate a "true" description of an observation into a "false" one. Relativistic physics has acquainted us with the new notion of the "metrical field" which is *apt to replace the old ether* as a carrier of electro-magnetic waves, so that it appears to be quite appropriate to reconcile "etherists" and "non-etherists."

Following a remark of Hermann Weyl ("Was ist Materie?", Berlin, Jul. Springer, 1924, p. 63) it is possible to reduce to rest simultaneously all bodies in the world (however they are moving relatively to each other) by means of a topological transformation. Consequently there is no meaning in speaking even about relative motion of separate bodies, e.g. of the stars and the earth. All we can say is that the earth moves relatively to the surrounding field, to the "star-compass." Here I would remark that even a relative motion of the earth to the surrounding field only has a meaning if the world is anisotropic around the earth: for a *spacial isotropic field can always be considered as being statical*.

The Miller effect shows us that rigid rotation does not leave the light-paths invariant; in other words, *that isotropy of the field and isotropy of the light-paths are not equivalent*. If rigid motion, that is to say, the *metric field*, is isotropic, then light-motion is not, and vice versa. Consequently the light-paths do not coincide with the minimal lines of the field. Although the Theory of Relativity in its present form holds for this coincidence, relativism in general leaves open the possibility of light-motion differing from quickest motion (as has been stated by Prof. Whitehead). Light only loses its exceptional qualities and quickest motion becomes an unreachable or at least unreachd limit, not only for material, but also for electro-magnetic motion, and in general for each form of motion which transports energy. But instead of being contradictory to the idea of relativism, this difference on the contrary agrees much better than the special Theory of Relativity with the modern view that matter and light are only gradually differing forms of energy.

Until now it has been impossible to say whether the Miller effect is due to translational or to rotational motion. In the first case the effect should vary periodically in time with the two periods of one day and one year, in the second case it should remain constant. From the point of view of the field-theory of matter the second case would mean a statical anisotropy of the field, whereas the first case would lead to an anisotropy varying in time, namely, a turning around the world lines of terrestrial matter, the latter being supposed to be reduced to rest.

In any case the Miller effect has shown us (according to a remark of Prof. G. Mannoury) that *the field, or the ether, or empty space, whichever you call it, plays an integrant part among the causal relations of physical phenomena and thus is not so very "empty" as it is supposed to be*.

Non-reversible Transmission.

ATTENTION has been directed to the possibility of non-reciprocal relations in the transmission of radio waves between two wireless stations (NATURE, by Prof. E. V. Appleton and M. A. F. Barnett, March 7, p. 333, 1925). Such a possibility appears at first sight to be contradicted by the general reciprocal theorem which states that the E.M.F. induced in A by unit current in B is equal to the E.M.F. induced in B by unit current in A . But this theorem rests on the assumption that all solutions are linear, and if this condition is waived, non-reciprocal relations are possible.

In confirmation of this the following examples may be cited which may have some bearing on the observed fact that transmission from west to east (on long waves at night), for example, England to Australia, appears to be considerably better than in the opposite direction. It should be noted that each of these are examples of "non-linear" effects. In the first case, consider a slab of ionised gas, the ionisation being assumed to be maintained by some external agency, for example, ultra-violet or X-rays. It can be shown that associated with this medium there is a critical frequency given by

$$n_0 = \left(\frac{e^2 N}{\pi m} \right)^{\frac{1}{2}}$$

where N = number of ions per c.c. (assumed for simplicity of one sign), e the charge, and m the mass of such ion. Neglecting the effect of collisions, then for frequencies n_0 the medium is transparent, but for frequencies less than n_0 the slab acts as a perfect reflector even for normal incidence. The physical reason for this is closely associated with the radiation pressure exerted by the electromagnetic waves on the medium. Thus in the neighbourhood of n_0 the rate of increase of momentum of the ions (due to the E.M. forces in the wave) is equal to the rate of change of momentum in the waves, where these are supposed to be completely reflected, so that the wave is totally reflected by mechanical reaction against the moving ions.

Consider now two radio stations A and B , one on each side of the slab. If the frequency of the emitted waves is n_0 or less than n_0 , neither station will be able to communicate with the other.

Now suppose the slab of ionised gas to be moving from left to right with a velocity v . So far as the slab is concerned, the frequency of the waves emitted by B will appear to be increased and those by A decreased. The slab will be transparent to waves from B but not to those from A , that is, B will be able to communicate with A , but A will not be able to communicate with B . Alternatively, we may treat the problem as an exercise in relativity with the same ultimate result.

The other example is more complex and depends upon the existence of a steady magnetic field.

A slab of ionised gas is again the mechanism by which the irreversible effects are produced. But in this case we assume that the ions have a velocity of drift, say vertically downwards (in the direction of the Z axis), that the normal to the electric wave is in the direction of the X axis, say right and left, and that the steady magnetic field, H_y , is at right angles to both, that is, in the y direction.

Under these conditions the electrons in the downward stream will be subject to two average forces, (a) a force at right angles to their velocity, and at right angles to the steady magnetic field H_y (this force will be in the X direction), and (b) a force due to the radiation pressure of the wave in the positive or negative direction according as the wave is moving

from left to right or vice versa. In the former case the two forces conspire in producing a motion in the ions, and in the latter, if H_y , V , and E are suitably arranged, they cancel. The reaction of the ions on the incoming wave will then be different according as the wave moves from left to right or vice versa. In the latter case there should be no work done by the radiation pressure on the ions, and therefore no loss of energy in the waves, in the former case work is done and a consequent loss of energy ensues.

The amount of reflection will be different according as the wave approaches from the left or from the right, and an irreversible effect is produced.

T. L. ECKERSLEY.

Marconi Works,
Chelmsford.

The Future of the British Patent Office.

DR MARTIN'S courteous letter in NATURE of September 12 calls for some reply, for although on questions of history we are in the main in agreement, yet when, as he says, we come to close quarters, he fails to reproduce my argument quite accurately.

Dr. Martin says, for example, that my two basic principles are not necessarily antagonistic. This I asserted, but said that for administrative purposes they could not be treated as co-equal, for the two types of administration would differ fundamentally. If the institution of new industries is the proposed object of our patent law, as I think is clearly the case from the provisions in the 1919 Act, the application form would have to be altered. The applicant would be required to affirm, as he used to do, that he was in possession of an invention which was not in use in the kingdom, and which it was his intention to introduce at the earliest opportunity. The official search certificate would state to what extent, if at all, the applicant's claims appeared to conflict with descriptions or claims in British specification of patents in force or with pending applications of concurrent or prior date. The case of applications under the International Convention would have to be reconsidered. The preferential treatment of the foreigner has always seemed to me contrary to the policy of our patent law. The validity of patents when granted would depend—(a) in cases where commercial working was shown, upon the state of the art in the kingdom at the date of the letters patent, and (b) where the patentee relied upon his specification, upon the state of public knowledge in the kingdom. In the latter case the patentee would be bound to show good reason why his patent had not been put into practice.

It is not, therefore, correct to say that since perfection in practice cannot be attained I recommend no search at all. My view is that, where one inventor fails, others should be encouraged to try again. For this purpose the official search must be brought into harmony with the revised statutory definition of novelty.

The anonymous letter which I quoted was intended to show that the world-wide search was breaking down and that, in the opinion of one well informed in American practice, a radical change in the statutory definition of novelty was the only solution of the difficulty. All bibliographical evidence tends to support his opinion.

Again, Dr. Martin does not agree with the thesis "that when security is at its highest, restraining power is necessarily at its lowest"—but my statement was "that as a general rule when security is at its highest the other factor will be little or none at all." The percentage, however, of really great inventions which pass scathless through the fire of the examining staff

is very small, and their commercial value depends, not upon an examiner's report, but upon the homage paid by all men of science to the path-breaker who opens a new road of research for the benefit of mankind.

E. WYNDHAM HULME.

Old House, East Street,
Littlehampton.

THE present Patent Office search, extending back for fifty years for novelty, is, as Mr Hulme says (NATURE, September 5, p. 356), really useless, and a fuller search ridiculous. To the inventor it is irritating; and it is of little value to the manufacturer, for before he gives a high price for the monopoly or spends much in adapting his plant and designs for using it, he, as a prudent man, will want something more.

Of course the granting of letters patent for overlapping existing protected inventions should be avoided, but that is all that is required. It should be open to any one to use the invention, or part of it, if he can show that it, or the part of it he is using, is old in the sense that it has actually been used; and a patent should not be invalidated because it, or part of it, has been described or figured a long time ago and forgotten until rediscovered by much "fever of the brow" and expenditure of time of the searchers.

TRAVERS J. BRIANT

The Old Cottage,
Wick, Littlehampton, Sussex.

Analysis of the Arc Spectrum of Copper.

STARTING from the constant frequency differences in the copper arc-spectrum, suggested by Rydberg, I have recently been able to deduce the values of a large number of new terms of that spectrum. My paper in the *Philosophical Magazine* (vol. 69, p. 951) has shown that copper gives a spectrum which is far from simple, and the further data now obtained show even greater complexity.

The new terms can be divided into two sets, those of the first set all being positive and combining with one or both of the known abnormally high d -terms. This set contains several terms already used in my paper. The inner quantum numbers are of course definite except in those cases where combinations with both d_2 and d_3 occur. The second set of terms consists altogether of negative terms which each combine with three or more of the first positive set, giving lines the wave-numbers of which differ from the calculated by not more than two-tenths of a wave-number. Altogether, about 125 lines are accounted for by these new terms. The inner quantum numbers of the negative terms can be deduced, though with some uncertainty, from their combinations with the positive terms. The values of the terms are as follows, the probable nature and inner quantum numbers being given with each

5026 2 ($j=4$)	- 95 2 (3)
5656 7 (2 or 3)	- 640 2 (p'_3)
6278 2 (4)	- 1276 4 (p'_1)
15709 8 (2 or 3)	- 8690 0 (3)
17345 2 (4)	- 8819 7 (3)
17763 9 (p_2)	- 8870 1 (3)
17901 8 (d'_3)	- 8960 1 (3)
18581 9 (d'_2)	- 9619 1 (p'_2)
18794 1 (4)	- 9708 6 (3)
20005 5 (s'_1)	- 9758 9 (p'_2)
20745 2 (2)	- 9785 0 (3)
21154 7 (4)	- 10890 7 (p'_2)
21364 3 (p_1)	- 10996 5 (p'_2)
22194 0 (p_2)	- 14722 0 (5)
23289 4 (4)	- 14760 1 (5)

NO. 2917, VOL. 116]

As yet I have been unable definitely to arrange many of these terms together either as doublets or quartets. It is evident, however, that quartets are involved. The difficulty arises partly from the large separations which are common in the copper spectrum and make estimations of relative intensities of lines of a multiplet uncertain. The complete analysis should afford tests of the theory of negative terms suggested by Russell and Saunders in their recent paper on the calcium spectrum.

Dr. L. A. Turner, of Harvard University, has recently suggested to me a possible explanation of the abnormally large inverted d -terms in the copper spectrum 51105 5 (d_3) and 49062 6 (d_2), based on considerations brought out in a paper by Pauli (*Zeit für Phys.* 31, 10). If we consider these terms as being due to the displacement of an electron from a 3_{32} or a 3_{33} group to the 4_{11} group, which is then closed, the atom might be considered as in a d -state. The inversion would be accounted for since the 3_{33} position is of higher energy than the 3_{32} position. Moreover, the formula $\Delta\nu/R = (z-s)^{1/2} a^2/3^4$ (Sommerfeld, p. 449) should yield a screening constant s approximately equal to 13.0, which is the value given by the separation of M_{32} and M_{33} for atoms of high atomic number. The value found is $s = 13.6$, which is suggestively close, considering the large extrapolation, and the approximation involved in considering the two electrons in the 4_{11} ring as having the same effect in the two cases.

Dispersal of Butterflies and other Insects.

IN the issue of NATURE for September 5, Mr. E. P. Felt in his interesting article on the "Dispersal of Butterflies and other Insects" says, "It is quite possible that some insect movements are direct responses to a migration impulse." As bearing on this point, the following incident, which occurred some years ago, may not be without interest.

I was walking through a field of standing wheat that was growing on the Downs near Walmer, Kent, the sun was just below the horizon, the air warm and still, when I noticed that moths were rising from the wheat and flying vertically upwards until they were lost to sight. On closer inspection, I found that vast numbers of the silver Y moth (*Plusia gamma*) were buzzing about among the wheat stems and that individuals were continually leaving their fellows and taking the upward flight. Although the larva of *P. gamma* will feed upon a great variety of low-growing plants, such as nettles, docks, and so forth, it is most unlikely that such numbers could have found sustenance on the weeds that might be growing in a fairly well kept wheat field, and the inference is that the moths had assembled among the wheat stems with the purpose of migration, and by their upward flight were seeking a favourable wind current to assist them in their journeyings in the upper air.

The incident, moreover, is not an isolated one, for Richard South describes a similar happening (*Entomologist*, 1880, p. 42) which he had witnessed in the Isle of Wight: the insects were, he believes, the same species, but in his case they were rising from furze bushes.

ROBERT ADKIN

"Hodeslea," Meads,
Eastbourne.

Fifty Years' Evolution in Naval Architecture and Marine Engineering.¹

By Sir ARCHIBALD DENNY, Bart.

AFTER Watt's invention of the separate condenser, many years elapsed before the next considerable step in marine engineering—the introduction of the compound steam-engine. This was natural, as steam pressures were too low to make compounding profitable. The first record I can find of compounding was John Elder's *Brandon* in 1854, and progress thereafter was not very rapid; but when I began my apprenticeship, in 1876, the old box boiler had been replaced by the now highly appreciated Scotch circular return-tube boiler, supplying steam to two-cylinder compound engines at about 60-lb. pressure. It was not then found profitable to carry more than about 25 in. of vacuum. Auxiliary machinery was almost non-existent.

As to types of marine engines—in the Navy, for protection reasons, horizontal machinery was not uncommon, while in the mercantile marine, for screw ships, the vertical type was practically universal. In paddle-steamers for river and coast service, of which there were many, the beautiful oscillating engine, which had the advantage of taking up little room lengthwise, was still built; but the diagonal engine was more common, either with single cylinder and haystack boiler or compound two-cylinder.

Returning to sea-going vessels, the *Propontis*, a vessel built in 1864, was re-engined at Fairfield with triple-expansion three-crank engines designed by the late Dr. Kirk in 1874, with boilers working at 150-lb. pressure; but the boilers, Rowan's water-tube, proved unsatisfactory, and in 1876 new Scotch boilers of 90-lb. pressure were fitted. The first really successful triple-expansion three-crank job, the *Aberdeen*,² was built in 1880 by Robert Napier and Sons, and fitted with engines and 125-lb. pressure boilers designed by Dr. Kirk. The re-engining of the *Propontis*, however, marked the opening of a new era, which only developed slowly at first, due in some measure to the then rules for the thickness of the boiler shells and furnaces.

The next great step was the introduction of the Parsons turbine. None can forget the tremendous interest created by the appearance of the 34½-knot 100-ft. *Turbinia*, at Spithead Review in 1897. I felt that here was the engine we had been looking for to use in fast cross-Channel work, and it was a great gratification when Sir Charles Parsons and Captain John Williamson arranged with my firm that we should join in a venture to build and run a Clyde river-steamer fitted with turbines; the *King Edward*, put on service in the spring of 1901, was the result—the first commercial turbine. Before that, however, in 1898, the Parsons Marine Steam Turbine Company received an order from the Admiralty to build the *Viper*, and Messrs. Armstrong, Whitworth, on their own account, built the *Cobra*, engined by Parsons. Both of these were torpedo-boat destroyers, and the *Cobra* was purchased by the Admiralty.

Following the *King Edward* and *Queen Alexandra*,

the *Queen* for the Dover-Calais service and the *Brighton* for the Newhaven-Dieppe service were the first cross-Channel turbine steamers put in service in 1903. They also were most successful, and the turbine as a commercial engine was fairly launched, a great tribute to the genius of Sir Charles Parsons and his courage in overcoming the many initial difficulties. The decision, taken early in 1905, to fit turbines in the large Cunarders *Lusitania* and *Mauretania*, built by Messrs. John Brown and Messrs. Swan and Hunter respectively, was a very bold and momentous one fully justified by the success of these vessels; it was a tremendous step to take from the smaller vessels already built and tried, to these leviathans crossing the stormy Atlantic. In 1905 the Admiralty also decided on the general introduction of turbines in all classes of warships.

The earlier turbines were all fitted as direct drives and hence to vessels of fairly high speed, when the revolutions were not too low to spoil the efficiency of the turbine or so high as to spoil the efficiency of the propeller. But from the first it was felt that some means of gearing down the propellers was absolutely necessary; Sir Charles Parsons' conversion of the *Vespasian* in 1909 from reciprocating to geared turbine gave the answer required and marked another new era.

In 1897 Dr. Diesel began developing his internal-combustion engine, depending for the ignition of the charge of heavy oil not on electric sparks, hot tubes, or bulbs, but on the heat generated by compressing the air charge. Immense developments have taken place in this direction. Initially the greatest progress was made with this type of engine on the Continent. My information is that the first successful ocean-going motor-ship was the *Vulcanus*, built in 1911 by Werkspoor of Amsterdam for the Anglo-Saxon Petroleum Oil Co., while the first completed in Great Britain was the *Jutlandia*, built in 1912 by Barclay, Curle and Co.

While Great Britain may have been slow at first in taking up the Diesel, certain types—such, for example, as the Doxford and the Cammell Laird-Fullagar—are purely English. Another purely English one (which, being a combination of steam and oil, is exceptionally interesting) is the Still engine, of which that on the *Dolus*, built by Messrs. Scott of Greenock for Messrs. Alfred Holt and Co. of Liverpool, has been successful. The first double-acting four-stroke cycle marine engine in Great Britain was developed at the North-Eastern Marine.

While the turbine developed from the fast passenger-vessels direct driven, to the slow cargo-boat with gearing, the Diesel started in the slow cargo-vessel and is developing towards the faster liner, of which the *Aorangi* of the Union Steamship Co. of New Zealand, built this year by the Fairfield Co., is, at the time I am writing, the most notable example.

The foregoing is the briefest of brief outlines of the changes in the main engines of ships, but the development in auxiliary machinery has been of tremendous importance and extent. In no direction has advance been greater than in the use of electricity on board

¹ From the presidential address delivered at Southampton on August 27 before Section G (Engineering) of the British Association.

² Messrs. Augustine Normand, Havre, have now proved to me that Benjamin Normand fitted a Seine passenger steamer with triple-expansion engines in 1871, and fitted at least two more successfully before 1874.

ship. In 1884 the *Arawa* and *Tanui* were fitted with incandescent electric lighting with stand-by oil lamps. The total power used was about 30 horse.

What developments there have been since then! Instead of the feeble 20 kilowatts, hundreds of kilowatts are now in use on a vessel of the same size, and the current is used not only for lighting, but also for ventilating, local heating, cooking, and for driving small machinery of all kinds, including frequently many of the important engine-room auxiliaries; in fact, in some vessels practically all the auxiliaries are driven by electric motors.

The fuel consumed in developing the power of these auxiliaries is now such an important proportion of the total fuel consumed that their design and installation is becoming, to a certain extent, a separate branch of engineering. To show the importance of a thorough study of this auxiliary-power question on board ship, I have been informed that in a large intermediate passenger-ship the consumption of fuel for auxiliaries is reported as exceeding 10 per cent. of the total consumption, and that 15 per cent. or more is not uncommon in some other vessels.

In types of boilers the development has gone from the old box form with safety valve opening inwards to prevent them collapsing when cooling, to the well-known and most extensively used Scotch marine circular boiler with return tubes. But always there were inventors working at the water-tube boiler, and several were constructed which proved successful. The Haystack was an early example, and those of Yarrow, of Thornycroft, and of Babcock and Wilcox may be named as types. In my own experience Yarrow and Babcock have each been used in fast cross-Channel steamers with absolute success, and, apart from the great user of water-tube boilers, the Royal Navy, water-tube boilers are being used increasingly in oversea merchant-ships. For land stations they are in great demand, fitted with mechanical coal-stokers or with pulverised coal or oil firing, in units of such enormous size and with steam pressure so high that steam drums have been built and used 34 ft. long, 4 ft. internal diameter, and 4 in. thick. Shall we see such boilers on board merchant-ships? I have no doubt we shall, though I would not care to express any opinion as to the ultimate highest steam-pressure which will be used, but 500 lb. is in sight.

Superheating of steam was early recognised as a very desirable thing, but it took many years to produce a reliable superheater, and then there were lubrication and other difficulties in reciprocating engines which had to be surmounted. In the case of turbines certain of these difficulties were non-existent, and turbines are peculiarly suited to the use of superheated steam. Another economical advance is pre-heating of air, which is now being pushed much further than ever, but with which the name of Howden will always be associated. Stage feed-water heating is also being very fully carried out.

Fuel-oil firing of boilers has been very largely adopted in steamships, with a marked gain in speed and, when oil is marketed at certain figures, with economy of cost as compared with coal, not only on account of its relatively smaller weight consumption, but also on account of the reduced crew required and the more regular

speed obtained, hence shorter time at sea. But in considering the relative advantages of steam- and motor-driven ships one must remember that an oil-fired steamship, in the event of oil soaring in price, may be converted to coal-burning, while in a motor-ship the owner has not that option.

As to powers developed by the main engines in any one steamship, from the 2000-3000 I.H.P. in good class passenger-ships of 1875 to the 75,000 I.H.P. we now find in the most powerful merchant-ships, or more than 140,000 in naval vessels, is a stupendous step.

Turning now to the ship herself and to naval architecture. I crossed to the United States to see ships' behaviour in heavy weather in December of 1882 in the *Parisian*, of the Allan Line, and returned in the same month by the *Alaska*. The latter was the "crack ship" at that time, and was 500 ft. long, the former was 440 ft. long, and they were considered enormous ships. The *City of Rome* was 560 ft., but was not so fast as the *Alaska*. They were all single-screw ships.

Mr. Foster King read a paper at Philadelphia, U.S.A., in 1912, in which he divided ships into three groups:

- (a) Atlantic passenger-ships (the longest ships).
- (b) Passenger-ships on all other routes.
- (c) Cargo-ships.

He obtained from the owners and registry books particulars of thousands of ships, and plotted them on diagrams on a base of years and with lengths of ships as ordinates. From these diagrams he concluded that the growth of "the largest ships in the world" might be fairly represented by straight lines in each group; that group (a) ships grew at the rate of 66 ft. in ten years, and group (b) 50 ft. in ten years. He observed, however, that after 1897 special vessels in (a)—namely, the fast Atlantic ferry—grew much more rapidly, at the rate of 150 ft. in ten years. For cargo-vessels (c) the rate of growth was about 30 ft. in ten years.

Taking Mr. King's (a) line, in 1875 the longest ship was about 475 ft., while, owing to the above-mentioned offshoot of the Atlantic ferry-boats, in 1912 it was round 900 ft. The *Majestic*, the present longest ship, is 915.5 ft. Reading from the (b) line, in 1875 the longest ship was round about 425 ft. In 1912 it should have been 610 ft., but was actually 570, and he remarks in explanation that "one of the usual pauses was occurring." The *Oronsay*, on the Australian trade, is the present longest (b) line boat at 633.6 ft. The *Empress of Canada*, on the Pacific, is 627 ft. long. As to cargo-ships—general traders—in 1875 a 3000 dead-weight carrier was a large ship; the more usual size was 2000-2500 tons. Now, 7000 to 8000 is the ordinary size, 10,000 is not uncommon, and many exceed that latter dead-weight.

In dealing with the growth in breadth of ships, Mr. King remarks that about 1875 the fashion in passenger-ships was about ten beams to length, but that after 1880 proportionate breadth became rapidly greater. An analysis of data available to me confirms this view, and that it is not now uncommon to find a proportion of eight beams to length, or even seven and a half.

The draught increased along with the increase in length, and the ports were constantly improved in depth, while new dry docks and floating docks kept

pace. Perhaps no better example can be given than the port of Southampton with its "longest in the world" floating dock.

Increase in draught is usually the most economical way of increasing carrying capacity or speed, hence the desire of naval architects for ample depth in ports and canals. When a curve of draught for the same proportion of depth to length is drawn with length as a base, it is seen at once that draught is proportionately less for the longer ship, and, as Lloyd's original tables were based on the current practice of the day, it is to be presumed that practical sea experience is responsible for this. Mr. Foster King's 1912 analysis of practice, as might be expected, shows the same thing. In the early 'eighties, however, experience was limited to about 400 ft. in length, and subsequent experience has shown that these and the longer steamers might safely be loaded deeper than the original rules contemplated.

Let us now turn to consider the change in the provisions for the comfort and convenience of the passenger. In the earlier days of steamships the first-class were in a poop, and the accommodation was very much in the style of the old sailing-ship—a row of cabins at each side with the dining-tables in the centre. There was an open-ended bridge and a fore-castle, where the officers and men were accommodated. Gradually, in later vessels the poop joined the bridge, and then the bridge joined the fore-castle, and the vessels became awning-deckers or spar-deckers. Then in later ships fore-castles again appeared, and midship houses developed into bridge-houses; then poops were fitted, to go once more through the same programme. Thus, as size increased, deck after deck has been added, until in the largest vessels the old names of bridge, upper, main, lower, and orlop no longer suffice, nor are they truly descriptive, and the decks are lettered A, B, C, D, etc.

The navigating bridge of a modern high-class steamer is an inspiring sight, with gyro compass probably fitted with an automatic quartermaster, "tell-tales" from the engine-room giving the revolutions of the engine and the direction of turning, similar "tell-tales" to the rudder head showing the angle of the tiller; the steering gear, now fitted aft, is controlled by a "telemotor," first invented by A. B. Brown of Edinburgh; wireless rooms, wireless direction-finder, and it may be underwater microphones for finding the position from underwater land bells; probably an outfit of telephones communicating from the bridge to the various chiefs of departments; automatic indicators showing the water in all holds and ballast tanks, and means for closing all watertight doors below deck in event of fog or collision.

Returning for a moment to the cargo-steamer—I have already dealt with the growth in size, but there are many other changes in these ships. Sails having practically disappeared, we find the place of masts taken by Samson posts and gantries; indeed, very many modern vessels, built for special trades, look more like a building berth in a shipyard than a sea-going steamer. The equipment has much improved both in the engine-room and on deck, and cargo appliances are quite different. But an important change is in the question of fullness of

block. For a considerable time the shipowner seemed to think in terms of £'s per ton dead-weight. This inevitably led to fuller and fuller blocks, until 0.83 was not uncommon; result—a low speed and a great uncertainty as to date of arrival at a port if any bad weather was encountered. Of course, block must be coupled with length, for the longer ship may have a fuller block, but round 400 ft. a block of 0.76 is now much more fashionable, with the result that, while the dead-weight lifted at one time on the same length of vessel is less, yet the higher speed and the greater regularity of time on the voyage, due to the ability to keep up a reasonable speed in bad weather, make the finer vessel a more economic proposition.

A most interesting and important type of special trader is the bulk-oil carrier or oil-tanker, which has developed quite a special technique in design, construction, and fastenings. Originally oil was carried in cases, but, starting with quite small bulk-oil carriers, we now find oil-tankers among the mammoth dead-weight carriers of to-day. Bulk grain, coal, and especially ore carriers, involve also quite special considerations in stability, and strength to resist concentrated loads in the last mentioned, of which type the highest development is to be seen on the Great Lakes of North America.

I have not referred at all to the tremendous changes which have taken place in the Royal Navy; that in itself would take more time than I have at my disposal. In main engines, however, the lines of development have been much the same as in the mercantile marine, while in the vessels themselves their purpose is so different that no comparisons can be drawn. But their design has not been without its influence on the merchant-ship in many details, and there are several directions in which the work at the Admiralty has had a commanding influence on naval architecture in Great Britain.

We may now turn to the technical training of the marine engineer and naval architect. Until the founding of the John Elder chair of naval architecture and marine engineering at the University of Glasgow, the technical education available to apprentices in private works was provided practically entirely by evening classes under the South Kensington Science and Art Department. Many of those men who, for at least a generation, were responsible for the great strides made in the technical efficiency of the twin industries received their professional education at these classes. These classes are still doing good work. Of course even before special chairs were established, B.Sc. courses in engineering were open to students, but only a few bursary or moneyed students could take advantage of them. For generations the Royal dockyards have taken care of the technical instruction of their apprentices, and schools for their instruction were, and are, at work in every dockyard. I can only stop to note the foundation of the Royal School of Naval Architecture and Marine Engineering at South Kensington. The best students from each dockyard were sent there for the first time in 1864, to receive a training in higher science and mathematics of a severity unmatched in any college.

Without proper technical education an efficient corps of designers and of research workers could not be main-

tained, and considerable and important has been the research work guided by the Admiralty, by our technical institutions, by Lloyd's Registry, and by many private firms and individuals.

In research, to no two men are we more indebted than to Dr. Wm. Froude and his son, Mr. R. E. Froude, for the experimental work done by them on ships' resistance and screw propellers. The British Association in 1868 appointed a committee to consider stability, propulsion, and sea-going qualities of ships, and of that committee Dr. Froude was a member, the others being Merrifield, Galton, and Rankine. The committee recommended experiments on actual ships, but Dr. Froude dissented and gave it as his opinion that model experiments were of value and were much cheaper to carry out, describing some he had made in 1867. In 1868-69, on the suggestion of Sir Edward Reed, then Chief Constructor, the Admiralty agreed to bear the cost of the construction and the working costs of the tank at Chelston Cross, Torquay. This tank started work in 1871, Dr. Froude acting as chief, and he gave his services gratuitously as long as he lived. On his death Mr. R. E. Froude took over charge, continuing and expanding his father's work. The results were freely communicated by him, with the full consent and encouragement of the Admiralty, to the Institution of Naval Architects in a series of valuable papers. The Torquay tank was ultimately dismantled and transferred to Haslar, where the good work is continuing.

There are now, besides the Government tank at Haslar, the following Froude tanks in Great Britain, in the order of age—Denny (Dumbarton), Brown (Clydebank), William Froude (Teddington), Vickers (St. Albans), and Parsons' have also a smaller open-air tank at Newcastle: that is six; and there are in Italy, Germany, France, Sweden, Russia, Austria, Japan, and the United States other eleven, a total of seventeen, and it may be claimed that tanks have had more far-reaching effect on design than any other means of research.

Yet, when one considers the research carried out on ferrous and non-ferrous metals, that claim may be disputed. Time fails me to do more than indicate to you the history of mild steel. While steel had been used in shipbuilding at an earlier date, our present material came into daily use in merchant-ship building in the late seventies of last century, and I can remember the interest taken in the *Buenos Ayrean*, the first steel Atlantic ship, built in 1879. With the considerable reduction in scantlings allowed by the Classification Societies, mild steel rapidly displaced iron in ship construction. But still we were warned that it was unreliable if worked at a blue heat, and some failures were recorded. Further improvement in manufacturing methods, however, finally gave us a material of great reliability and easily worked. The limits of 28-32 tensile strength and 20 per cent. extension in an 8-inch specimen have been standard now for many years, though steels of greater carbon content and higher tensile strength have been used: and as Young's modulus is practically the same for all ordinary carbon steels, these higher tensile steels could be used in conjunction with milder steels without disadvantage. But there is now another mild carbon steel on the market which has a higher elastic limit, the use of which

is just beginning; it is claimed that it will ensure further advantageous developments in reduction of weight of hull.

Sir Robert Hadfield's invention of high-manganese steel gave a fresh impetus to research in ferrous alloys; and now we have alloys of nickel, chromium, vanadium, tungsten, and other metals, each with its own special use either in construction of ships and their machinery or in the machine-shop for tool-steel, thus still further advancing the science and art of shipbuilding and marine engineering.

Other powerful factors in the development of the merchant marine were the Board of Trade, the Classification Societies, and the technical institutions and societies.

The Board of Trade is charged by statute with the duty of seeing that ships are safe and sufficient for navigation. The individual surveyor is legally responsible, and it is he who must certify safety and sufficiency; but, for co-ordination purposes, there is a Consultative Branch at Whitehall which issues "Suggestions and Instructions" to the surveyors as to how they should carry out their duties. These "buff books" have in practice largely the same effect as the rules and regulations of the Classification Societies.

Practically every maritime nation has a Registry or Classification body or bodies of its own, but in Great Britain that type of organisation has been earlier and more fully developed than in other countries. Lloyd's Registry has a world-wide name and has had a profound influence on design not only in this country but also all over the world. This leads me to speak of standardisation in shipbuilding and engineering. The first work of the B.E.S.A., when it was established in 1901, was the standardising of ships' sectional material. Order was thus brought out of chaos, the number of standards, sections of all kinds and sizes, was fixed at 175, and the steelmakers reported that a saving of at least 5s. per ton was the result. A revision in 1918 reduced the standard sections to 115. A recent piece of work of the B.E.S.A. is the standardising of the tail-shafts of ordinary cargo-vessels, which standards may also be applicable to many passenger-ships. The taper of the shaft to take the propeller boss is also fixed. It can easily be seen what a saving this would mean in the case of damage at a distant out-port, where, were these standards adopted, only a few spares need be kept, or even the spare of one steamer could be used for another with the same diameter shaft, and thus in the case of damage the present long delays in an out-port waiting for replace parts would be avoided.

The influence of the Institution of Naval Architects on the progress of design cannot be exaggerated. Founded in 1860, there has been a constant stream of valuable papers read and discussed at the annual meetings; naval architects and marine engineers were glad of the opportunity of presenting the results of their experience to their fellows and of profiting by the discussion of their ideas. Now there are all over Great Britain—at Liverpool, Newcastle, Southampton, Glasgow, and other centres—similar institutions, contributing to the advance of the science by their meetings and published transactions.

Radiometric Determination of the Temperature of Mars in 1924.

By Dr. W. W. COBLENTZ, Bureau of Standards, Washington, D.C.

THE main problem in the radiometric programme of 1924 at the Lowell Observatory, as stated in the article in NATURE of September 19, p. 439, was the measurement of the radiation from Mars. For this purpose most of the measurements were made at the 640-inch focus of the 40-inch Lowell reflector, which gave an image of the disc of Mars about 2 mm. in diameter. The receiver of the vacuum thermocouple was 0.23 mm. in diameter, or about $\frac{1}{8}$ of the diameter of the disc of Mars at opposition. This permitted the isolation of small areas on the disk of the planet and revealed hitherto unobserved and perhaps unexpected temperature conditions.

By means of a series of screens of water, quartz, glass, and fluorite, the radiation emanating from a planet, e.g. Mars, was separated into spectral components and the radiation intensities determined in the

observed Martian water-cell transmissions (W.C.T.'s in Table 1); (2) by the law of spectral radiation and the ratio of the Martian spectral radiation components, A : B; (3) by plotting Very's observed lunar temperatures against the observed lunar spectral radiation components, A : B, and extrapolating to the observed ratios of the Martian components; (4) by calculating the lunar temperatures (Menzel) from the lunar water-cell transmissions, using the fourth power law, plotting these temperatures against the observed lunar spectral radiation components, A : B, and extrapolating to the observed ratios of the Martian spectral radiation components; and (5) by plotting the lunar temperatures (which were obtained by calculation from the lunar water-cell transmissions, using the fourth power law) against the observed lunar water-cell transmissions and extrapolating to the observed Martian water-cell trans-

spectral regions of 0.03 to 1.4 μ , 1.4 to 4.1 μ , 4.1 to 8 μ , 8 to 12.5 μ , and 12.5 to 15 μ . In this paper the ratios of the spectral components of the planetary radiation at 8 to 12.5 μ and at 12.5 to 15 μ (A : B) are of special interest. The radiometric work was carried out in collaboration with Mr. C. O. Lampland, and the complete results are given in the June and July issues of the Journal of the Franklin Institute.

In view of the conflicting opinions regarding temperature conditions on Mars, it was desirable to reduce the radiometric data by various methods and also to have someone not connected with the work to make some of the calculations. The writer therefore submitted to Dr. D. H. Menzel a considerable portion of the observations obtained in 1924 for calculation, thus supplementing the work of 1922, as mentioned in NATURE of September 19.

Martian temperatures were derived by the following methods: (1) by the fourth power law of black body radiation (Menzel), using Russell's formula and the

missions. (A more complete discussion is given in the *Astronomische Nachrichten*, June 1925.)

In addition to these calculations, planetary temperatures were inferred from comparisons with the earth, in which it is shown that the temperature of the solid surface of Mars would be expected to rise almost as high as that of the earth. In fact, with much clearer skies and with less air convection in some of the darker places on Mars, especially in the temperate and in the frigid zones, where the insolation is so prolonged, the temperature should be considerably higher than observed on similar regions of the earth.

The temperatures derived by these various methods of reducing the data are in good agreement and indicate conclusively that the equatorial temperature of Mars, at perihelion, was considerably above 0° C. When one considers the difficulty in establishing the temperature of a terrestrial object within 10° C., it seems truly remarkable that these various methods appear to be so close in agreement in indicating that the temperature

of Mars rises above 0°C . This is an extremely important deduction, for the possibility of vegetable life on Mars depends partly upon the question of temperature conditions.

A weakness in the method of using the spectral components is owing to the fact that the spectral range of the planetary radiation is narrow, and the spectral transmissions of the atmosphere and of the fluorite screen at 10 to 11μ are not known with sufficient accuracy to determine the temperatures to better than 10°C . However, it is a new and an independent method for obtaining temperature levels.

Ordinarily it would be considered sufficiently close to have determined the temperature level to within 10°C . However, in the present problem the temperature estimates range about 0°C ., and the question at issue is whether the average estimates place the value somewhat above 0°C ., for the question of the possibility of vegetation on Mars depends partly upon this temperature estimate. While the results obtained by this method give a wider range of temperatures than the other methods, its usefulness in supplementing the other methods seems evident.

The dark regions were found to be hotter than the bright regions; also the east limb or sunrise side was observed to be cooler than the west limb or afternoon side of the planet. The temperatures of the bright areas range from -10° to 5°C ., while the temperatures of the dark areas range from 10° to 20°C ., or perhaps even higher. The average temperature of the apparent centre of the disk, including the bright and the dark areas, was found to be about 15°C ., verifying the estimate of 10° to 20°C . based upon the radiometric measurements of 1922. There was but little seasonal change in temperature (average 14°C .) on the centre of the disk during the six weeks from August 1 to September 14. While the measurements were in progress it was winter in the north polar regions. Under these conditions the temperature of the irradiated north polar region was down to -70°C ., or perhaps even lower, and continued at this temperature during the course of our measurements. Similar temperatures occur in our arctic regions during the winter. On the southern hemisphere it was early summer, and the temperature of the south polar region, as observed through the overhanging atmospheric mantle of mist or perhaps ice spicules, was -60°C . However, in view of the fact that it was the summer season, with melting snow and a receding polar cap, it is reasonable to assume that the temperature of the solid surface at the south pole was up to 0°C . The complete paper by Coblentz and Lampland in the Jour. Franklin Institute (June and July 1925) gives data on climatic conditions on various parts of the surface of Mars: (1) the bright and dark regions on the centre of the disk; (2) the east and west limbs; and (3) the north and south polar regions.

To the writer the apparent temperature of -60°C ., as measured through the water cell during the early Martian summer in the south polar region, is not inconsistent with the commonsense interpretation of the visual observations (receding polar cap, melting ice) indicating a temperature up to 0°C ., but is a remarkable verification of the presence of an atmosphere containing a mantle of ice spicules or perhaps water vapour

("mist"), which prevents the escape of planetary radiation from the solid surface. It is to be noted that our interpretation of planetary temperatures is based upon the radiation of wave-lengths 8 to 15μ which emanates from the planet. Evidently this overhanging mantle is of considerable extent and is perhaps in the form of a thick mist or fog which is opaque to these wave-lengths. For it is well known that the highly attenuated water vapour in our atmosphere is quite transparent to radiation of wave-lengths 8 to 15μ , whereas mist and fog prevent the transmission of infra-red rays of long wave-length.

The temperature of the south polar cap changed but slowly during July and August. However, in September the temperature began to rise rapidly, and by October the water-cell transmissions decreased to 30 per cent. or even lower, indicating a temperature of 6°C (true temperature about 15°C .). This is extremely interesting in view of Rev. T. E. R. Phillips' recent paper on this subject (Mon. Notices R.A.S., 85, p. 179, 1924), in which micrometric measurements are given showing that the melting of the snow proceeded slowly during July, but that the cap diminished rapidly in size during August and September, and became very small in November.

This rapid rise in temperature of the south polar region from -60° (the temperature of the isothermal layer of the polar canopy; 0°C . if interpreted from the visual observations of the receding cap of melting ice) in July to 10°C . or even higher at the Martian summer solstice (on October 5) is perhaps one of the most important results of this investigation. From a consideration of the prolonged insolation on the south polar region, such a temperature rise is to be expected.

On the west limb the observed temperature was -2° to -8°C . at the beginning of August, when there was a small dark phase. When there was no dark phase on the west limb the temperatures ranged from 0° to 6°C .

Perhaps the most interesting series of measurements relate to the east limb or sunrise side of the planet. During the first part of August, the east limb was irradiated for an hour or more before turning into view. Under these conditions the observed temperatures of the eastern limb range from -10° to -20°C . At opposition, August 22, when there was no dark phase, the temperature was down to -45°C . At the conclusion of the series at the 53.3 foot focus, on September 12, when the dark phase was barely perceptible on the east limb (illuminated surface 0.976), the temperature was -60°C . How much lower the temperature falls, and whether this very low temperature is owing to setting the receiver on the atmospheric envelope, remains to be determined.

From the low temperatures recorded at the poles, and the small atmospheric envelope, it appears that the temperature of the night side of Mars may fall below -70°C .

This study of the seasonal changes in temperature, especially of the southern hemisphere of Mars, was continued late into November by Mr. Lampland, using the same radiometric equipment and galvanometer employed by us during the preceding months. He reports that the water-cell transmissions of the radiation from the north polar region continued unchanged, at

70 to 80 per cent., indicating a temperature of about $-70^{\circ}\text{C}.$, as was to be expected with winter on this hemisphere.

On the other hand, the water-cell transmissions of the radiation from the south polar region decreased from the high value observed in the early part of September to 30 per cent., or even lower, in November and December, indicating a temperature of 10° to $15^{\circ}\text{C}.$, or even higher. Granting that some ice still remained at the pole, there would be a temperature gradient for which a correction should be made. On this basis, the water-cell transmissions would be still lower and the temperature of the south polar region would be higher than indicated by these measurements.

The observed high surface temperatures on Mars

may be accounted for on the assumption that these dark areas contain vegetation having the properties of the tuft-forming grasses of our high prairies, and the tussock mosses and lichens of our dry tundras, which have a high absorptivity for solar radiation and a low thermal conductivity. The assumption of the presence of such a type of vegetation is in harmony with the visual observations, which show changes in the colouring of the dark areas with changes in the seasons, and it is in agreement with the lower intensity of insolation on Mars. The radiometric observations indicate that during the summer season on Mars, temperature conditions at noonday are not unlike the bright cool days on this earth, with temperatures ranging from 5° to 15°C or 40° to $60^{\circ}\text{F}.$

Sir William Thiselton-Dyer and the "Flora Capensis."

THE publication in the *Kew Bulletin* (No 7, 1925, pp 289-293) of an account, by Sir W. T. Thiselton-Dyer, of the commencement, progress, and completion of the "Flora Capensis," affords a fitting opportunity of recalling Sir William Thiselton-Dyer's work at the Royal Botanic Gardens, Kew, and more especially the work he has done for the British Empire in advancing the knowledge of its botanical riches in the domain both of economic and systematic botany. With regard to the systematic study of the Colonial floras, the two works which are especially associated with his many years of office at Kew are the "Flora Capensis" and the "Flora of Tropical Africa." Proposals for both these works were made by Sir William Hooker, so long ago as 1863, when *inter alia* he put forward a proposal for a flora of the "South African Colonies" in ten volumes and a flora of the "West African Colonies" in two volumes. Out of the former proposal has come the now completed "Flora Capensis" and from the latter the "Flora of Tropical Africa," which, when finished, will occupy eleven or twelve volumes.

The "Flora Capensis," as Sir William Thiselton-Dyer states, had, however, actually been commenced at the suggestion of Sir William Hooker. It was undertaken by Dr. Harvey, "sometime Treasurer of Cape Colony," the professor of botany in the University of Dublin. He "undertook to print and publish the Flora at his own risk and cost, trusting chiefly to colonial subscriptions for a repayment of the outlay." Dr. Sonder, of Hamburg, "gladly accepted Dr. Harvey's offer to share the authorship." Volume 1, dedicated to Sir George Grey, K. C. B., "Governor and Commander-in-Chief of the Colony of the Cape of Good Hope," bears the publication date 1859-60. Volume 2 was published in 1862, and Volume 3 in 1865. The following year Prof Harvey died, and Dr. Sonder, who took no further part in the work, died in 1881.

Sir Henry Barkly, Governor of the Cape of Good Hope from 1870-77, himself an ardent naturalist and fellow of the Royal Society, urged upon Sir Joseph Hooker, who had succeeded his father as director of Kew, the completion of the work of Harvey and Sonder, and Sir Joseph Hooker suggested to Mr. Dyer, as he then was, that he should undertake the completion of the work of the Cape Flora. As, however, he was at that time assisting Sir Joseph in sub-editing the

"Flora of British India," he was unable to entertain the proposal, and later, being appointed to the post of assistant director of Kew in 1875, he was again precluded from taking up any particular part of the Flora himself. Sir William, however, was able to enlist the aid of numerous contributors in carrying on the work; but the general task of supervising and editing a work which was part of a project initiated by Kew, appeared to him to fall naturally within the scope of his official duty, and so after a long interval the "Flora Capensis" was again started.

Sir William points out as a striking fact, that in the volumes published by Harvey a very large number of the species are only represented by a single collection. It was highly desirable to have more copious material to work upon, if only to supply more ample data for geographical distribution, and thanks to Sir William Thiselton-Dyer a numerous body of contributors was marshalled, and they rendered valuable service in sending home material for the adequate working out of the Flora. Among these Peter MacOwan and Dr Harry Bolus deserve particular mention.

Sir William, in his article, refers to the fact that upwards of ten thousand specimens have been named and catalogued for South African botanists and collectors in connexion with the work of the Flora, and that during twenty years, from 1877, the time of one member of the Kew staff, Mr. N. E. Brown, was almost exclusively occupied with the determination of these fresh accessions of South African plants. Sir William bears eloquent testimony to Mr. Brown's work, pointing out that from his complete mastery of the features of the flora and of South African topography "he has been the invaluable mainstay of my own share in the undertaking."

It was in 1877 that Sir William was able to start the work on the Flora on an effective basis, and he was fortunate in being able to secure the co-operation of South African contributors, including Dr. Harry Bolus, who undertook the Ericaceæ; Dr. E. P. Phillips, who worked out the Proteaceæ; and Miss E. L. Stephens, who worked out the Penæaceæ. The Orchids, which should have been worked out by Dr. Harry Bolus, could not be carried out by him and were undertaken by the late Mr. R. A. Rolfe of the Kew Herbarium staff. Other contributors of whom Sir William makes special mention were Mr. J. G. Baker, who elaborated

the "Cape Bulbs," and Mr C. H. Wright, assistant in the Herbarium, Royal Botanic Gardens, Kew, who sub-edited the whole of the contributors' manuscript.

It is interesting to note that Sir William Hooker estimated both the number of volumes and the financial support that would be needed to carry out the work with remarkable accuracy. He fixed the number of volumes at ten, which is the number now published, and he also estimated that ten thousand would be the number of species to be dealt with. The actual number, however, is 11,705, and of these 2016 are described for the first time.

The "Flora of Tropical Africa," like the "Flora Capensis," though it owes so much to the energy and sagacity of Sir William Thiselton-Dyer, was commenced before he was able to assume any control over its preparation. Originally it was intended to be the joint work of Sir William Hooker and Prof. Daniel Oliver, Keeper of the Kew Herbarium; but the work was handed over to Prof. Oliver, and the first three volumes appeared in 1886, 1871, and 1877 respectively. Then, as with the "Flora Capensis," came a long break, and it was not until Sir William Thiselton-Dyer was able to take the matter in hand that the preparation of this flora could be resumed. As an outcome of his activities a new volume of the Flora appeared in 1898 devoted to the petaloid monocotyledons, Volume 7 of the entire work, this being the first volume to be produced under Sir William's editorship. This was followed in due course by Volume 4, published in two sections, Volume 5, Volume 8 and Volume 6, Section 1, the latter, which was published in 1913, being the last to appear under his editorship. The Flora has been continued under the editorship of Sir David Prain, and only some two parts, dealing with the grasses, now remain to be published.

The work entailed in arranging for the collection and naming of the material for these two great works would, it might well be thought, be sufficient to have occupied the full attention of the director of Kew, upon whose time there are so many calls with regard to botanical problems both at home and abroad; nevertheless, Sir William found time to initiate yet another work, *The Kew Bulletin of Miscellaneous Information*, for the purpose, more especially, of disseminating knowledge about the economic botanical

products of the Empire. The *Bulletin* was started in 1887 and is still in a flourishing condition, despite one or two times of difficulty—one of which was during the War, when an attempt was made to suppress it on the mistaken idea of economy.

Sir William's preface, which we quote, fully explains the scope and purpose of the work:

"It is proposed to issue from time to time, as an occasional publication, notes too detailed for the Annual Report on economic products and plants, to which the attention of the Staff of the Royal Gardens has been drawn in the course of ordinary correspondence, or which have been made the subject of particular study at Kew. It is hoped that while these notes will serve the purpose of an expeditious mode of communication to the numerous correspondents of Kew in distant parts of the Empire, they may also be of service to members of the general public interested in planting or agricultural business in India and the Colonies.

"W. T. THISELTON-DYER,
"Director.

"1st January 1887."

The present condition of the Kew Museums is also largely due to Sir William Thiselton-Dyer. Originally started by Sir William Hooker, the collections grew apace and fortunately they came under Dyer's purging hand, with the result that much encumbering dross was removed and the economic products were displayed to the best possible advantage. At the same time the Museum guides were produced and put on sale, in order that the public might be provided with accurate information on the wealth of the vegetable kingdom and the economic products derived therefrom.

These, with the two African floras and the *Kew Bulletin*, are a record of service which is of the highest importance, not only in the development of our knowledge of the botanical resources of the Empire but also because of the impetus this gives to scientific research in botany.

Such services as these, and many other activities displayed by Sir William Thiselton-Dyer in various botanical enterprises, have rarely been surpassed in value and importance by the labours of any other public servants to whom the British Empire owes so much.

Obituary.

PROF. FELIX KLEIN, FOR. MEM. R.S.

FELIX KLEIN, who was born at Düsseldorf on April 25, 1849, died on June 22, 1925. He had been professor at Göttingen since Easter 1886, having previously been at Erlangen (1872-1875), Munich (1875-1880), and Leipzig (1880-1886). With a trenchant expository style, revealing a forceful genial character, he wrote on almost every branch of mathematics; he was editor of the *Mathem. Annal.* from the time of the death of Clebsch (1872), originator of the "Enzyklopadie" for mathematics and mathematical physics (from 1895), and, in his own country, worked incessantly for a living co-operation of physics, engineering, and mathematics, and (since 1908) to bring the teaching in the schools into touch with current scientific problems. He was also a constant traveller and lecturer, was

twice in America and many times in England, since 1873. His exceptional personality appeared at once after his student days at Bonn; he took his doctor's degree at the age of nineteen; issued the second part of Plücker's book on line-geometry at the age of twenty; by the end of 1871, when he was twenty-two, had published eighteen original papers (some of these with Lie); by the end of 1875 he had published forty. Many of these are still mines of suggestiveness; his Erlanger Programm (1872) has been translated into English, French, Italian, Polish, Russian, and Hungarian.

Klein's mathematical papers were published, under his own supervision, in three volumes, in 1921-1923, containing more than two thousand beautifully printed pages; in these is inserted a running personal commentary; in effect, a detailed account of his scientific

thoughts and aims from the age of eighteen, with many references to colleagues and pupils. These volumes, intensely interesting from so many points of view, are the sufficient and authentic basis for a review of his life.

It appears, what will be new to many, that Klein's life was lived under a resolve, never relinquished, made when serving Plucker as assistant for his lecture on experimental physics, to devote himself to physics. He desired only, first, as a preparation for this, to make himself acquainted with all branches of mathematics, in order to trace the connexions of their leading ideas, and to be in a position to raise physics to a higher plane. The notes enable us to trace how this resolve was modified by circumstances, and only realised in the work of others whom he inspired: two leading causes are brought out—his pre-eminently sympathetic temperament, and a serious breakdown of health at the age of thirty-three. It seems clear that he worked mainly by discussion with friends and pupils, and by lecturing. His vivid account of the time spent with Lie in Paris in the early part of 1870; his evident interest in meeting Sylvester, Cayley, Clifford, and Ball at the British Association at Bradford, in 1873, and the reference to the happiest time of his productive activity (1876–1880), when he, from Munich, and Gordan, from Erlangen, each travelled a long way to enjoy on Sundays a *Mathesis quercupolitana* at the half-way Eichstadt, are examples of what appears throughout.

Now such discussions were conditioned by the interests of his colleagues, as his early work had been influenced by his teachers (Plucker, Clebsch, Weierstrass, Kummer); and thus Klein was led into giving his publications a form quite other than physical. We see, however, how he fought to maintain his early resolve, particularly in the manner of approach to Riemann's theory of functions, and, later, in his volume (with Sommerfeld) on the motion of the top. This begins in a mathematical way; but, in the course of the thirteen years occupied in its publication, reaches a very technical plane. But besides this concession to his surroundings, it appears that, first at Munich, and then more seriously at Leipzig (in 1882), he was warned that he could not continue to work with the same intensity, and must needs live on a different level. Thus he began to limit himself to the supervision of the long series of books and lectures, on almost every subject of mathematics and mathematical physics, of which the detailed work was carried out by others.

Meanwhile Klein's unceasing anxiety for the organic working union of physics and mathematics expressed itself in administrative ways. He secured, one can imagine with what trouble, a co-operation of German Academies, to bear the responsibility for the "Enzyklopadie", he travelled hither and thither to secure competent contributors, especially to England (there being, as he explains, no sufficient sympathy in Germany between mathematicians and physicists), himself undertook the part dealing with mechanics, in connexion with which he obtained the translation into German of Routh's "Dynamics," Lamb's "Hydrodynamics," and Love's "Elasticity." In his own Göttingen, later on, were founded a Physical Institute, with the help of German manufacturers, and a society for the encouragement of mathematical physics; to him it appeared

"Mechanik, überhaupt angewandte Mathematik, kann nur durch *intensive Beschäftigung mit den Dingen selbst gelernt werden*; die Literatur gibt nur eine Beihilfe." He took every opportunity, by visits to conferences and lectures, to keep in touch with engineers and physicists, he organised vacation courses for teachers to give their teaching the proper modern orientation; and finally, from 1908, he gave his attention to the schools, and lamented the ruin the War had wrought in the extensive preparations made for an international campaign.

Little need be said in this place of the brilliance of the mathematical papers, especially of Klein's earlier years. If the reader agrees with Poincaré, in a letter quoted here, "Je ne crois pas qu'une démonstration puisse être résumée; on ne peut en retrancher sans lui enlever sa rigueur et une démonstration sans rigueur n'est pas une démonstration," he will find here, also, Klein's reasoned reply. Nor need we think that his international aims were not genuine because of his evident patriotism, and his desire to see Göttingen "über Alles." These are desires which he would have commended in others. For we are bound to feel that his life was devoted to a very real and practical problem of our time, and that he worked at it loyally and unremittingly—namely, how to bring under as few points of view as can be grasped by one man the astonishing output of physical and mathematical thought in the last hundred years. The difficulty is not that the ideas involved are so wide apart, on the contrary, they are very cognate—Bohr uses the ideas of the theory of Abelian functions, and would use the approximation theory elaborated by Lagrange, combined with Planck's physical results, to construct an explanation of spectrum lines; Einstein uses an absolute differential calculus, tracing its origin to Lie's work for continuous groups as well as to Riemann's thoughts on geometry, with a realistic outlook such as was discussed by Mach, to found a new calculus for the motion of material bodies. It is probably the case that the grooves in which the mind of the physicist can move, to elaborate his theories, have generally been worn by the imagination and systematising efforts of the mathematician, who, in rare cases, may be the same person; and it is certain that only by the development of all aspects of thought can progress be continued. But how shall one man secure an adequate understanding of all that may concern him in the work of so many others? Must we say that the answer is that only if the civilised world can continue in patience and amity to co-operate to this end, can the end be reached?

At least we owe honour to the commanding personality and penetrating intellect of Felix Klein, for his life's devotion to the solution of the problem.

COUNT GOBLET D'ALVIELLA.

THE death of Count Goblet d'Alviella on September 8 as the result of a motor-car accident is announced from Brussels. Count Goblet d'Alviella was born in 1846, and for some time was professor of the history of religion at the University of Brussels. He had a distinguished career in public life successively as a member of the Chamber of Deputies, member of the Senate, of which he became vice-president in 1912, and Minister of State and member of the cabinet during the War.

He held the degree of doctor of philosophy, and the Universities of Edinburgh and Glasgow had conferred upon him honorary degrees. In 1891 he delivered the Hibbert Lecture, his discourse being published afterwards under the title, "A Lecture on the Origin and Growth of the Conception of God as illustrated by Anthropology and History." He was the author of a number of books, including "Sahara and Lapland. Travels in the African Desert and the Polar World," which was published in an English translation in 1874, and "The Contemporary Evolution of Religious Thought in England, America, and India," published in England in translation in 1885.

Goblet d'Alviella's most important work, however, was "La Migration des symboles," published in Paris in 1892, and in an English version with a preface by Sir George Birdwood in 1894. This book embodied material originally appearing in the *Bulletin de l'Académie Royale de Belgique* and elsewhere, but in much extended form. The study of forms of symbolism had at that time fallen somewhat into disrepute owing to the unscientific and highly speculative methods of earlier writers such as Depuis and Creuzer, but Goblet d'Alviella placed it on a secure footing by the application of inductive methods and comparative study. As Sir George Birdwood said in his foreword, he "raised the inquiry to its proper position as a department of archaeological research, producing a work destined to exert an abiding influence on the whole future of the study of symbolism"—a prediction which time has not belied. This book still remains the best study of the principal symbols employed in early decorative art, such as the swastika, the triskele, the tree of knowledge, and the winged disc. It is interesting to note that while Goblet d'Alviella derived each of such symbols in the main from a single origin in some one centre, he was prepared to admit that in certain areas and in favouring circumstances they probably had arisen independently.

WE regret to announce the following deaths.

Prof. C Chandler, formerly professor of chemistry at Columbia University, New York, a former president of the American Chemical Society, and an original and an honorary member of the Society of Chemical Industry, aged eighty-eight years.

Prof. Albert T. Clay, professor of Assyriology and Babylonian literature in the Graduate School of Yale University, and president of the American Society for Oriental Research, on September 14.

Sir Francis Darwin, formerly reader in botany in the University of Cambridge, on September 19, at seventy-seven years of age.

Dr. William C. Farabee, curator of the American section of the University of Pennsylvania Museum, distinguished for his archaeological and ethnological work in South America, on June 24, aged sixty years.

Prof. W. S. Hendrixson, professor of chemistry since 1890 at Grinnell College, Iowa, known for his contributions to the study of electrometric methods in chemistry, on July 1, aged sixty-six years.

Senator E. F. Ladd, formerly professor of chemistry at North Dakota College and president of the Agricultural Experiment Station, on June 22, aged sixty-five years.

Dr. Georg von Mayr, professor of political economy and statistics in the University of Munich and an honorary member of the Royal Statistical Society, aged eighty-four years.

M. Auguste Pavie, an honorary corresponding member of the Royal Geographical Society, who carried out important explorations in Indo-China, Siam and Upper Annam, adding considerably to our knowledge of French possessions in Asia, aged seventy-eight years.

Prof. F. Ranwez, professor of pharmaceutical chemistry in the University of Louvain and president of the International Congress of Pharmacy held at Brussels in 1897, aged fifty-nine years.

Dr. Georg A. Schweinfurth, distinguished by his geographical, botanical, and ethnographical work in Africa, on September 19, at eighty-eight years of age.

Dr. A. Tuckerman, known especially for his bibliographic work in the United States on the literature of the spectroscope and of thermodynamics, on May 25, aged seventy-seven years.

Prof. Charles Vélain, the first occupant of the chair of physical geography in the Faculty of Sciences of the University of Paris and founder of the "Revue annuelle de Géographie," on June 6, aged eighty years.

Prof. J. B. Woodworth, of the Department of Geology and Geography at Harvard University since 1890, a pioneer in the scientific study of earthquakes, who was also known for his work in the glacial geology of Brazil and other areas, on August 4, aged sixty years.

Current Topics and Events.

At the recent meeting at Southampton of the British Association, it was a subject of general remark that modern scientific thought shows a striking drift away from the facile generalisations of the Victorian age. The progress of research in the sciences bearing on agriculture illustrate this change to a very marked degree, and the report of the Rothamsted Experimental Station for the years 1923-1924, which has just been issued, bears witness to the number and variety of the investigations in progress at the premier institution for agricultural research in Great Britain. The list of scientific papers published from the Station during the period reached the remarkable total of fifty-eight. The Physics Department alone was responsible for thirteen papers, of which three appeared in the Proceedings

of the Royal Society. Under the various sections of this report dealing with the many physical and biological factors which enter into plant growth, we are constantly met with references to the interplay of contending forces. In the soil, in place of absolute values assigned to specific plant nutrients (*teste* Page), colloidal calcium- and other complexes now figure as the battle-ground of warring ions, and in the biological field, as the work of Cutler and Thornton has shown, much depends on the ebb and flow in the bacteria-protoczoa conflict. Superimposed on all these come the vagaries of the weather, an extraordinarily difficult factor to measure. The work of evaluating all these factors falls to the Statistical Department, the activities of which (perilously esoteric!) are ably directed by Mr. Fisher.

THE outlook of Rothamsted is, in the main (and rightly) academic, but if there is any department the concern of which more intimately touches upon existing economic conditions, it is that dealing with the physics of the soil, in charge of the Assistant-Director, Dr Keen. Costs of "cultivations"—man and horse labour—may approach three-fourths of the total cost of home-grown crops, and, at the present rates of wages, the homeland is almost hopelessly handicapped—a topic, by the way, prominently brought to notice at the Southampton meeting by Sir Daniel Hall and Sir Henry Rew. It may be hoped that the new Research Institute in Engineering recently founded at Oxford will find it possible to enter into intimate co-operation with the fundamental work on cultivations now going on at Rothamsted. We notice a reference in the report to a matter of considerable public interest, and that is, the problem of exploiting, on a commercial scale, discoveries made in laboratories supported by large grants from the State. The Rothamsted authorities are happy in finding, in Lord Elveden, a patron who is willing to undertake the commercial development of the discovery made by Hutchinson some years ago of a method of making "artificial" farm-yard manure. The report also contains the details of the various field experiments which are in progress at Rothamsted, as well as full particulars of the interesting investigations conducted by Dr Voelcker at the farm at Woburn, the maintenance of which the Royal Agricultural Society somewhat precipitately jettisoned some years ago.

At the second Pan-Pacific Science Congress held in Australia in the summer of 1923, the invitation of the Japanese delegation to hold the third congress in Japan in 1926, under the auspices of the Japanese National Research, was accepted, and a preliminary announcement has recently been issued. The main objects of the Congress, like those of 1920 and 1923, will be the promotion both of co-operation in the study of scientific problems affecting the Pacific region and of the sense of brotherhood among the scientific workers of the countries concerned as a means of strengthening the bonds of peace among the Pacific nations. To these ends, the programme will consist largely of symposia upon selected subjects. Three discussions suggested provisionally for general sessions of the whole Congress deal with the physical and biological oceanography of the Pacific, radio-transmission in the Pacific region, and the geotectonics of the Pacific area, respectively. The provisional programme for the Division of Physical Sciences includes discussions, with special reference to the Pacific region, on solar activity, terrestrial magnetism, meteorology, the strand-line during Pleistocene and post-Pleistocene time, the correlation of Mesozoic formations, metallogenic epochs, volcanoes, and earthquake-proof constructions. The Division of Biological Sciences will probably discuss the floras and faunas of the various countries and islands of the Pacific and their relationships, plant successions and quarantines, the protection of aquatic animals, the genetics of live-stock and crops, particularly rice, the antiquity of

man, and the diseases of native races. Other suggested discussions deal with astronomical observations, earthquake observations, geodesy, oil-bearing formations, thermal springs, storage of cereals, green manuring, diseases of animals, anthropometry, tropical diseases and food, drugs, clothing, and housing in the Pacific region. It is stated that the committee authorised at the Congress in 1923 to effect a permanent organisation of scientific institutions of the countries of the Pacific has been set up. It contains representatives of the countries of the region and of the European powers interested in the Pacific.

THE International Commission of Eugenics is a body originally nominated by the International Eugenic Congress with power to co-opt additional members. The International Congress of Eugenics meets every five years, and the Commission was intended to afford eugenists opportunities for the exchange of views and mutual consultation at more frequent intervals. The fourth meeting of the Commission was held in London in July, the third meeting having taken place last year at Milan. The London meeting was attended by representatives from the United States, France, Holland, Belgium, Italy, Denmark, and Norway. Two important resolutions were agreed to, the first moved by Dr Davenport, the American representative, to the effect that, as every nation has a right to determine who shall be included in its body politic, so it is expedient that every immigrant-receiving country should inquire into the family and personal history of each would-be immigrant, and the second, also moved by Dr Davenport, that the standard pedigree chart devised by Miss Van Herwerden should be printed and published by the Commission as the best and most practicable form of recording such histories. Dr Collin, one of the Norwegian representatives, agreed to summarise the most recent theories as to the causes of the rise and fall of civilisations, and report on the subject to the next meeting of the Commission. Dr Mjoen, the other Norwegian representative, delivered an interesting lecture on the inheritance of musical ability. He showed clearly that it was impossible to explain this inheritance as the results of the passing on and segregation of a Mendelian factor. He adopted the device of postulating the existence of numerous factors inherited separately, these factors were, however, arbitrarily chosen and ill-defined.

In a report circulated by Science Service of Washington, D.C., which appears in *Science* for August 2, it is stated that a joint expedition of the Smithsonian Institution and Amherst College has discovered a crushed human skull associated with stone arrow-heads and the remains of mammoth and mastodon near the towns of Melbourne and Vero, Florida. Above the elephant stratum pottery was found among an accumulation of recent shells, and in the sands below, teeth of horse, camel, and sabre-toothed tiger, indicating a characteristic Pleistocene fauna. Dr. J. W. Gidley, leader of the expedition, is confident that the human remains were not buried in the

mammoth strata. The inference drawn is that the mammoth and mastodon survived in this area of Florida for some 10,000 years after those of which the remains have been recently discovered in Indiana and are assigned to the late Pleistocene. The result of further investigation of the evidence will be awaited with interest, and should it confirm the conclusion here stated, the late survival of the mastodon may serve as a possible explanation of the association of human remains with bones of the mastodon at Natchez, which those who deny high antiquity to man in America have hitherto been constrained to explain as due to burial or fortuitous causes and as affording no evidence for contemporaneity.

As agreed at the conclusion of the World Power Conference held at the British Empire Exhibition, Wembley, last year, the International Executive Committee met in July last for the purpose of discussing the future activities of the movement. An invitation to hold the second World Power Conference at Basel in 1926, on the occasion of the Internal Exhibition for Inland Navigation and Utilisation of Hydraulic Power, was refused on the ground that a longer period than one or two years was desirable between plenary sessions of the Conference. Meanwhile, however, it was decided to hold sectional meetings in various areas, under the auspices of the International Committee, to discuss programmes on specific subjects within the general conference programme. An invitation was accordingly sent to the Swiss National Committee to hold a sectional meeting at Basel in 1926 for the discussion of the development of hydro-electric power combined with inland navigation, the interchange of electric power between countries, the economic relation between hydro- and thermal power, railway electrification and electricity in agriculture, stress being laid particularly on financial and economic aspects. The International Executive Committee further recommended, as a means of securing the continuity of the Conference movement, that a *Journal of the World Power Conference* should be published at regular intervals. It was decided, subject to reconsideration at a later meeting, that the second World Power Conference should be held at Rome in 1930.

In the *Lancet* of September 12 there is an important paper on the experimental treatment of implanted malignant tumours of the rat, by Dr. Thomas Lumsden, of the Lister Institute. A short time ago, Dr. Lumsden published the results of the action of an anti-serum which had been prepared by injecting rats or rabbits with emulsions of ground-up cancerous tumours of mice. When such a serum was brought into contact with cultures of cancer cells, the latter were injured or destroyed. Normal serum had no such effect, and the cancer serum had no effect on cultures of cells other than cancerous. Thus a fragment of heart culture could flourish and beat in anti-cancerous serum. Dr. Lumsden, in his new paper, has extended these results to the possible therapeutic action of such anti-sera. When rats were inoculated on the foot with a fragment of Jensen rat sarcoma—a highly malignant tumour—the resulting new growth could

be made to disappear when the anti-serum was injected locally and prevented from diffusing itself through the body too quickly. Remarkable to say, the animal, after the cure of its tumour by serum, was found to be immune and could not be reinfected. When rats were inoculated on two of their feet, the resulting tumours both disappeared when the serum was injected locally into only one of the tumours. Further developments of this work will be awaited with interest.

THE probable rainfall in India during August and September, based on the weather in India in June and July, associated with the weather conditions in other parts of the world which are most likely to influence the coming rains in India, was issued on August 7 to the Government of India by the Director-General of Observatories. In both June and July the monsoon was normal in activity, the rainfall for the two months over the plains as a whole was about 5 per cent in excess of the normal. There was an excess of more than 50 per cent in Orissa, the United Provinces west, and the Punjab east and north; of 20 to 50 per cent in the United Provinces east, Baluchistan, Rajputana east, Central India east and the Central Provinces east; and a defect of 20 to 50 per cent in Kashmir, Sind, Berar, Hyderabad north and Mysore. In the remaining subdivisions the total rainfall of the period was within 20 per cent. of the normal. It is summarised that there is no strong reason to expect any large excess or defect in the total rainfall of August and September, either in north-west India or in the Peninsula. The Bombay correspondent of the *Times* reports, however, under date September 19, that the monsoon, which until a fortnight ago was favourable everywhere, shows signs of failing, and that rain is badly needed in many districts in the south of India.

AN adequate supply of pure distilled water is an indispensable requisite in all chemical and in most physical laboratories. If the consumption be very small and the degree of purity required be only "reasonable," the commodity can usually be purchased with impunity from the local druggist, but in all other cases it must be prepared in the laboratory. Common defects of the ordinary still are painfully slow rate of production, and "accidents" with the gas or water-supply. The patent automatic tin-lined stills supplied by Messrs. Brown and Son (Alembic Works), Ltd., of 9 Wedmore Street, London, N.19, as has been found from many years' experience, are free from these faults. The rate of distillation secured with this still is many times greater than that obtainable with any of the old-fashioned types, and the mechanical device, ensuring that the water-supply is turned on simultaneously with the gas-supply, makes the apparatus as fool-proof as possible; it does not, however, prevent minor mishaps due to fluctuating pressure in the gas and water mains. Such fluctuations are a source of great annoyance in many chemical and physical operations, and simple, cheap devices for counteracting them are badly needed. The new catalogue issued by Messrs

Brown and Son contains illustrations and particulars of stills heated by gas, steam, or oil, together with information concerning their output per hour.

IN Bulletins 746 and 747, the United States Geological Survey has published a Bibliography and Index to the "Geologic Literature on North America, 1785-1918," compiled by John M. Nickles. These two volumes will be extraordinarily useful to geologists all over the world. The flood of geological literature is so great that it is always difficult to keep pace with it, and an important work of reference such as this is what the late Prof. Cole would have called a very real aid to practical geology. It should be noticed that the publications indexed refer to the whole of North America from the West Indies to the Arctic and to the Hawaiian Islands. In Part I. the names of authors are arranged in alphabetical order, papers being listed in chronological order in each case. About 45,000 titles are indexed in this way. Part II. is a subject index and contains about 70,000 headings.

THE officers of the Röntgen Society for the session 1925-26 are as follows.—*President*, Dr. F. W. Aston; *Vice-Presidents*, Dr. Robert Knox, Mr N. S. Finzi, Prof A. W. Porter; *Hon. Treasurer*, Mr. Geoffrey Pearce; *Hon. Editor*, Dr G. W. C. Kaye, *Hon. Secretaries*, Dr. E. A. Owen, Mr Russell J. Reynolds

DR WILLIAM C. REYNOLDS, referring to his letter in NATURE of September 12, p. 394, states that data regarding the troposphere and stratosphere provided in Dr. G. C. Simpson's presidential address to Section A (Mathematics and Physics) suggest that the optical, electrical, and thermal zones probably coincide—a simple and important geophysical condition. An aeroplane observer at sunrise and sunset should, therefore, have three separate methods of determining the limits of the lower zone. Such data regarding the thermal zones as Dr. Reynolds had when writing his earlier letter appeared to place the stratosphere higher up.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned. An assistant lecturer and demonstrator in engineering and an assistant lecturer and demonstrator in mining and mine-surveying at the University College of South Wales and Monmouthshire, Cardiff—The Registrar (October 3) A senior lecturer in pure mathematics in the University of Cape Town—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, London, W C 2 (October 20). Junior technical assistants in the wireless experimental department of the Royal Aircraft Establishment—The Superintendent, R.A.E., South Farnborough, Hants (quoting A 79).

Our Astronomical Column.

BROOKS' PERIODIC COMET—A telegram from the International Astronomical Union Bureau, Copenhagen, announces the detection of this comet by Prof Tcherny at Kief Observatory; its position on Sept. 19 at 19^h 9.5^m Universal Time being R.A. 23^h 17^m 36.9^s, S. Decl. 5° 12' 11". The magnitude was 9.5, considerably brighter than the predicted value, which was about 12; there is therefore a possibility that the comet is not identical with that of Brooks. The R.A. is 18^m 49^s in excess of Prof. Dubiago's prediction the Decl. 15 3' south of it. The predicted elements were:

$$\begin{aligned} T &= 1925 \text{ Nov } 8, 5838 \text{ U.T.} \\ \alpha &= 195^\circ 48' 59.4'' \\ \Omega &= 177^\circ 25' 36.5'' \\ i &= 5^\circ 42' 44.6'' \\ \phi &= 29^\circ 0' 41.0'' \\ n &= 510.9845'' \end{aligned} \quad \left. \begin{array}{l} \\ \\ \\ \\ \end{array} \right\} 1925 \text{ O.}$$

The correction to T from the R.A. is -5 354 days. that from the Decl. +0 942 days. These are considerably discordant, and strengthen the suspicion of non-identity. If it is Brooks', the appropriate weights are 3 to R.A., 1 to Decl.; weighted mean -3 78 days.

The perturbations at the last aphelion passage were very large, the distance from Jupiter being less than 8 million miles. Curiously, Wolf's Comet made a similar approach at about the same time.

The following ephemeris for O^b is found from that of Dubiago by applying +18^m 49^s and -15 3'.

	R.A.	S. Decl.
Sept. 26	23 ^h 15 ^m 47 ^s	6° 1'
" 30	23 14 58	6 31
Oct. 4	23 14 34	6 57
" 8	23 14 33	7 20
" 12	23 15 0	7 40
" 16	23 15 56	7 56

On Sept. 26 the comet is due south about 23^h. Its distance from the earth is 0.9 unit.

MARS—Prof W. H. Pickering observed Mars last year from Mandeville, Jamaica, and gives in *Popular Astronomy* for August-September an interesting summary of his own and other observations. He reproduces some early photographs of Mars taken on ordinary plates in 1888 and 1890. Some of these show the prominent markings obliterated by a whitish veil, like Mr Wright's recent photographs on ordinary plates, this corresponds (as both observers noted) to the fact that terrestrial photographs on ordinary plates fail to show distant objects plainly visible to the eye, while red-sensitive plates show them. Others of the old photographs show the dark markings plainly, indicating that the clearness of the Martian atmosphere is subject to large variations. Prof. Pickering agrees with Mr. Wright in concluding that the atmosphere is denser and more extensive than was recently thought probable. He argues in the same direction from the recent thermopile measurements, which indicated a temperature well above the freezing point. As the desert regions showed a lower temperature than the maria, he conjectures that they are more elevated. Assuming a temperature gradient similar to that on earth, he gives the mean elevation as 8000 feet.

There are detailed descriptions of some of the large clouds that appeared in the equatorial regions at the last apparition. One of these was 1200 miles by 500 miles, its rate of motion being 24 miles per hour.

In common with several other observers, Prof. Pickering looks on the presence of vegetation on Mars as practically assured, and presumes that this implies the presence of at least some forms of animal life. There has been a pendulum-like swing in views on Mars, in the middle of the last century it was generally looked on as a miniature of the earth. Towards the end of the century the view of its non-habitability was widely held, now we notice a tendency to revert to the earlier view.

A CHIBCHA TEMPLE IN COLOMBIA—In 1924 an official Commission identified and investigated the site of the Chibcha Temple of Suamox, which was burnt in 1537 by the troops of Quesada, who had been attracted thither by reports of its riches. The Commission consisted of Gerardo Arrubla and General Carlos Cuerva Márques, the former of whom describes the results of these investigations in the English edition of *Inter-America* for August. By a careful examination of the chronicles and traditions and of trustworthy witnesses, and by exploration on the ground, the Commissioners were able to fix the site of this Temple of the Sun with certainty in the city of Sagamoso itself. Excavation confirmed the traditional account that it had been built of wood and had been destroyed by fire. Tradition also has it that the wood used had been carried from a great distance on the backs of the Indians. It was found that the wood of the temple columns does not grow in the valley or nearer than the plains. Each pillar was said to have been erected on the body of a sacrificed slave, and human remains with small objects of gold, stone, clay, and shell were actually discovered at the base. The temple was circular in form and had a diameter of 36 metres, a remarkable size considering the rudimentary architecture of the Chibcha.

THE ORIGIN AND DISTRIBUTION OF TREPPANNING—Dr Wolfel of Vienna has made an exhaustive study of the practice of trepanning among primitive peoples, of which Part I appears in Hefte 1-2, Bd xx, of *Anthropos*. The operation was practised in prehistoric Europe and in North Africa, it persisted in Albania and Serbia and among the Berbers. It occurs in Melanesia and New Guinea, and a number of skulls have been found in America which show that it was employed by the inhabitants of the Mississippi Basin, in Mexico, and in the Andean region. In the present section of his work, Dr Wolfel deals with Melanesia and New Guinea and America, and, after a comparative study, concludes that in these two areas it is an element in a common culture complex. In Melanesia and New Guinea its use is mainly surgical, especially for healing wounds caused by stone clubs or sling stones by removing fractured bone. It is also practised for epilepsy and headache, as a matter of fashion, and to secure longevity. It has also a magical implication. Essentially, however, it is to be connected with the use of the stone club and sling in war. Turning to America, the skulls which have been found, occurring even so far north as Lake Huron, show that trepanning was adopted as a method of dealing with a crushing blow, such as might be caused by a stone club or sling. Here also there is evidence of disease, and MacCurdy directs attention to traces of cauterisation. Although the existence of the sling in pre-Columbian America has been denied, there is sufficient evidence to call for the revision of this conclusion, e.g. in the Winland slingers of the Saga of Eric the Red, the Algonkin devil-head slings, among the Beothuk of Newfoundland, and so on. The existence and distribution of stone-headed clubs is also well attested. It is therefore to be concluded that trepanning is an element in a culture complex which was associated with the stone-headed club and coheres with the "two-class" system common to both the South Seas and America.

TEMPERATURES IN EUROPE DURING THE TERTIARY PERIOD.—A paper with the title "Der Einfluss der variablen Erdbahnelemente auf das morphogene

Warmebild Europas im Tertiär" is published in the 1924 year-book of the Academy of Sciences, Vienna. The author, M F Kerner-Marilaun, read the paper before the mathematical-physics class, and he deals with the influence of variable elements in the earth's orbit on the temperature distribution in Europe in tertiary times. Von Spitaler's calculations of temperature in pure land and sea climates were used to establish regions with extreme temperatures in tertiary Europe. For winter temperatures, values calculated earlier by the author were employed, while special formulæ were developed to obtain the summer temperatures, and from these results the temperatures for the places of thermal extremes were found. By the variations of flora in horizontal and vertical directions, the regional and zonal fluctuations of temperature caused by astronomical variations can be traced. It is not always possible to trace the influence of each heat wave in an oceanic climate, because other influences may mask the changes to be examined.

THE ORIGIN OF CONTINENTS—In *Die Naturwissenschaften* for July 31, Dr Otto Ampferer of Vienna discusses in detail the various possibilities arising out of the distribution of the continents. He accepts Wegener's conception of the sial and sima layers, but believes that there are probably more than two layers of different density, and that in particular a third layer, intermediate between sial and sima, may underlie the continents. If vertical movements alone are postulated, then the oceans may be due to simple sinking, either by bending without fissures, or by in-breaking with bordering faults. This corresponds with the requirements of the contraction theory, but it is pointed out that expansion would lead to a similar result, the continents being then due to relative uplift. The existing evidence of both compression and tension in the earth's crust implies that both processes have contributed to some extent at least. However, the tectonic study of mountain ranges has proved beyond doubt that very large horizontal displacements have actually taken place, implying that extensive regions of the continents have been bodily moved. Vertical movements alone cannot explain these extraordinary thrusts, and Ampferer believes that, in addition, horizontal movements, independent of those arising from compression, must be postulated. He shows that Wegener's displacement theory involves the difficulty that it provides no possibility of explaining two absolutely opposed processes: the first, the compression of the original uniform shell of the earth into a primeval continent collected around Africa; and the second, the subsequent break-up and dispersal of the land area into the continents of to-day. Wegener suggests for the cause of the dispersal only relatively feeble external forces. Ampferer insists that some entirely different kind of phenomenon is necessary. He does not discuss the recent views of Joly, Holmes, or Evans, all of whom have contributed to a possible solution, but he favours the idea that under-streaming currents within the earth may be responsible. Ascending currents beneath the continents would raise and split them, and carry the fragments in all directions; whereas Wegener's forces would lead to a definite direction of drift.

RAINFALL IN AUSTRALIA—The rain map of Australia for 1924, which is published by the Commonwealth, shows the distribution of precipitation for each month, and contains also a detailed map of the annual fall indicating excess and deficiency compared

with the normal. The year was similar to 1923 in its marked rainfall contrasts. In the north-western part of the continent there were severe drought conditions, while on the other hand, in eastern Australia, including Tasmania, there was abundant rain, making the year one of the most favourable on record for pastoral and agricultural interests. Winter was comparatively dry, but in August widespread rainfall set in and continued for three or four months. In December the rains decreased, and harvesting conditions were ideal in most parts. Over the continent as a whole, 27 per cent of the area had a rainfall above the annual average. This compares with 22 per cent in 1923, 21 per cent in 1922, and 63 per cent in 1921. In 1924, however, the excess above the normal was almost entirely confined to the eastern part of the continent.

TERRESTRIAL MAGNETISM—Several new propositions with regard to terrestrial magnetism are announced in the June issue of *Terrestrial Magnetism and Atmospheric Electricity*. The fact that magnetic storms increase in frequency with the sun-spot numbers has been known for some time, but Dr. A. Podder, of the Irkutsk Observatory, shows from an examination of the records of that observatory for the past thirty years that storms are more frequent in March and in September than in any other months, and traces this to the passage of the earth in those months through the plane in which the centres of maximum activity of the sun are situated. He finds there is also a daily variation in the frequency of storms, which is independent in character of sun-spot number and of season. During each storm the deviation of the compass is reduced, the dip increased and the horizontal component of the magnetic field decreased. With regard to "sudden commencements," Dr. L. A. Bauer finds from an examination of the records of 30 disturbances that while there may be cases in which they occur simultaneously at all points, the speed of propagation may be so low as 1000 kilometres per second along parallels of latitude and only 100 kilometres per second from the magnetic equator towards each magnetic pole.

THE PHYSICAL NATURE OF THE CORONA—The various theories as to the nature of the solar corona are discussed by Dr. W. Anderson in the *Zeitschrift für Physik* for Aug. 1. Taking into account the amount of light emitted by the corona, and the amount passing through it from the photosphere, he estimates that, if more than fifty per cent of the gravitational force acting upon the material of the corona is to be balanced by the radiation pressure, the total mass within one solar radius of the sun's surface must be less than 10^{18} grams. The theory of C. Fabry, which ascribes the continuous spectrum of the corona to diffusion of solar light by gases as in Raleigh's theory of the spectrum of light from the sky, does not explain the absence of Fraunhofer lines in the coronal spectrum, and is in other ways unsatisfactory. The hypothesis that gaseous particles fluoresce under the influence of the light of the photosphere is rejected, since the spectrum appears to be truly continuous, with a few bright lines, and not to be due to the superposition of a number of banded spectra due to fluorescence of different gases. It is very improbable that the coronal light is due to bombardment with corpuscular radiation of radioactive origin. The difficulty with the electron gas theory of the corona is that it requires a positive charge on the sun equal to the negative charge of the corona, and that under these conditions the extension of the corona could only be small. This difficulty may possibly be got over by assuming that Coulomb's law of electrostatic force ceases to hold for large distances. It is possible to test the universe square law of

gravitational force for large distances, but this is not possible in the case of electrostatic force, and it may perhaps fall off in such a way as to account for the structure of the corona.

SHEET GLASS PRODUCTION—Prof. W. E. S. Turner describes the modern production of sheet glass in a paper published in the *Journal of the Royal Society of Arts* for July 24. For many years, until quite recently, glass used for sheet had the composition SiO_2 72-74 per cent, CaO 12-14 per cent, Na_2O 12-14 per cent, the latter being mainly derived from soda ash. In two of the automatic processes recently introduced, a softer glass has been employed containing a higher percentage of sodium oxide. The presence of magnesia retards devitrification and tends to make more uniform the rate of change of viscosity. In Lubbers' process, the glass is melted in a large tank and is removed in 500-570 lb lots in an iron ladle. This is poured into a hot "drawing pot," really a shallow fireclay dish, and a "drawing head" is lowered in. On elevating the latter the glass is drawn up into a cylinder, which may attain a length of 36 ft and is usually 30 in in diameter. The cylinder is then split and flattened in the usual manner. Methods are now in use in which sheet glass is drawn directly without necessitating the formation of a cylinder. Two such processes are described. The Libbey-Owens process was inspired by the inventor watching a paper-making machine; molten glass is drawn from a trough over rollers on to a "flattening table," where it is annealed. In the Fourcault process, molten glass is drawn vertically upwards through a slot. The manufacture of plate glass dates from 1665 and the process has remained practically unchanged; the modified process used by Ford for manufacturing wind-screens for motor cars is described.

EXPLOSIVE GAS MIXTURES—Papers 8, 9 and 10 of the Safety in Mines Research Board deal with the very important matter of the ignition of firedamp (H.M. Stationery Office, Nos 8 and 9, 6d each, No 10, 4d). The work embodied in the reports has been carried out by Dr. R. V. Wheeler and co-workers. Papers 8 and 9 are intimately connected. It is shown that the mixtures of methane and air most readily ignited by a sustained source of heat are those containing an excess of oxygen. Such mixtures require a source of heat at a lower temperature and, moreover, a shorter period of contact (provided, of course, the temperature is above the ignition point). With other paraffin hydrocarbons (e.g. ethane, propane, butane, pentane) the mixtures most readily ignited by a similar source of heat contain an excess of combustible gas. The ease of ignition of paraffin hydrocarbon-air mixtures increases as the hydrocarbon series is ascended; the lag on ignition decreases under similar circumstances. Report No. 10 deals with firedamp explosions within closed vessels and the effects of turbulence, the latter being studied in relation to the maximum pressures produced and the time taken to attain the maximum pressure. Whereas considerably enhanced pressures can be obtained from weak mixtures of methane and air when they are turbulent, the most explosive mixtures (9-10 per cent methane) are not much affected even by extreme turbulence. The maximum pressure obtainable from any quiescent mixture of methane and air, initially at atmospheric pressure, when exploded in a closed vessel is about 105 to 110 lb. per square inch. The effect of turbulence is to increase this maximum pressure by about 4 per cent. On the other hand, with both weak and strong mixtures the effect of turbulence is greatly to increase the rapidity with which the maximum pressure is attained.

The Heating of Rooms.¹

THE Fuel Research Board has published a useful paper on the heating of rooms by Mrs Margaret Fishenden and Mr. R. E. Willgress. A room of about 4000 cub. ft. capacity, shaded from direct sunlight, and possessing a hearth and flue, was used. Air-heating was obtained by hot-water radiators or by luminous batwing gas flames placed about 6 inches above the floor. The air movement was then about $\frac{1}{2}$ to $\frac{1}{4}$ ft. per second. After entering the test-room, the two observers engaged in sedentary employment for at least an hour before the comfort feelings were noted.

With no source of radiation, a comfortable feeling of warmth corresponded with a temperature of air and surrounding surfaces of 65° F. One of 62° F. was too chilly, and 68° F. slightly too warm. This is the range for minimal evaporation of a resting clothed man in still air. Increased evaporation begins at about 73° F., and 72° F. was the temperature at which distinct discomfort was felt.

When the walls and floor were slightly cooler than the air, the air to give comfortable warmth had to be warmer, e.g. 66° F. for walls, etc., at 63° F., and 67° F. for 61° F. On the other hand, with walls, etc., at 66° F., 67° F., air temperatures of 63° F., 61° F. sufficed. When the walls, etc., were more than a degree or two colder than the air, chilliness combined with stuffiness was felt, but with the walls a few degrees in excess of air temperature, very comfortable conditions were felt. With the flue blocked, a feeling ensued of heaviness, airlessness, and blunted mental energy. Even with the flue open, air-heating was found to be far from ideal for mental work. The authors concluded that a sunless room cannot be rendered entirely pleasant by air-heating alone. They found that variation of wet bulb temperatures from 51° F. to 57° F. for a dry bulb of 65° F. had no effect on the comfort feeling.

With air-heating and air-flows of 2, 4, 6, and 8 ft. per second over the entire position of the observer, dry bulb temperatures of 69°, 72°, 75°, and 76.5° F. were needed to sustain comfort. The corresponding mean wet bulb temperatures were 60°, 62°, 64.5°, and 66.5°. As was pointed out by the inventor, the ratio between the rate of cooling of the kata-thermometer and the rate of cooling of a clothed man increases as the air velocity increases, because clothing exercises an increasingly important shielding effect as the air velocity rises. Draught exceeding 4 ft. per second became annoying, and distracted the attention from mental work.

Ideal conditions conducive to mental work were got in a room with south-west aspect by an air temperature of 64° F. to 68° F. with October-November sunshine and open windows, and a draught of $\frac{1}{2}$ to $1\frac{1}{2}$ ft. per second.

Radiation was studied by means of a modern gas-fire, and by an open wire electric heater placed under the chimney flue. Additional draught could be produced by a gas-ring in the flue; thus $2\frac{1}{2}$ to $4\frac{1}{2}$ changes of air per hour could be had. The air temperature was brought to the desired level, and the subject sat at various distances from the fire. While warm enough at an air temperature of 65° F. without radiation, at 60° F. a mean horizontal component of 30 B.Th.U. per sq. ft. per hour was

required to produce warmth, at 55° F., 75 units, at 50° F. 120 units, at 45° F. 170 units. Radiation figures well below or above these gave chilliness or warmth.

The most comfortable conditions were with 55° F. and adequate radiation, above this a slight feeling of mental lassitude was produced, and below it a feeling of too warm on one side, too chilly on the other. Below 45° F. it was impracticable by a fire to avoid this feeling. The alpine sun may, however, give one in a reclining position 500 B.Th.U. per sq. ft. per second—enough for an air temperature far below freezing point. It is the equable climate of Britain which makes open fires practicable. In countries where the outside temperature remains for months below freezing point, air must be heated, and a closed stove or central heating is used. A low temperature radiator heated by bunsen burners below red heat and 6 ft. square in size was found very pleasant. This is equivalent to wall panel heating, which has been found successful in the Bush building at Aldwych, London.

Two cylinders of water 8 inches in diameter and one-third the height of an average man were used, one of bright polished copper, the other coated with lamp black, and the effect of clothing on the loss of heat from these cylinders was studied. The water was kept stirred. In still air, a single woollen vest reduced the heat loss to 66 per cent. of the unclothed black body, with an additional white serge garment to 45.5 per cent., with further black serge coat to 38.5 per cent. In a draught of 2 ft. per second the reductions were to 60, 42, and 36 per cent., and in one of 6 ft. per second to 48.5, 32, and 25.5 per cent. respectively. The three garments together cut down the absorption of radiation to 20 per cent. of that which was absorbed by the unclothed black calorimeter.

The last part of the paper deals with the cost of heating. The hot-water radiator with coke boiler is most economical for continuous heating of a small room (1000 cu. ft.), or for a larger room (4000 cu. ft.) where people cannot gather round a fire. An open fire is cheapest for the larger room when occupied by a few people who can gather near it, because air-heating is not then necessary. For intermittent heating, the hot-water radiator is cheapest for a small room, and open coal, coke, or gas fire for a larger room. "Whatever the method adopted, the cost will be closely allied with the completeness of insulation of the rooms." An air space between two thicknesses of brick and double windows are two suggestions made.

Here we come up against that conflict between stagnant artificial heat and good health which is not considered by the authors, but is established both by physiological research and the experience of open-air life. We should aim at the least degree of heating with which we can do sedentary brain-work or skilled hand-work in comfort, and the maximal amount of window ventilation. If clothes were adjusted to individual need in offices and factories, and the feet kept warm by small local units of heat, far less air-heating would be necessary, and far more window ventilation made possible, and in this way, and by abolishing smoke pollution and securing more sunlight, catarrhal infections would be reduced. It is the open-air life, and not sheltering indoors in heated rooms, that keeps catarrhal diseases off and the general health up.

Thunderstorms and Other Features of the Weather.

MR. BROOKS has compiled a very valuable monograph on the thunderstorms of the world¹. A "day with thunder" is the unit employed, and records are used from 3265 stations, 2680 being in Europe. Maps show the percentage of days with thunder for the whole year, and for each half-year. It is assumed that thunder can only be heard up to ten or twelve miles, and that on the average it will only be recorded when occurring within six miles of any station. Mr. Brooks shares the general opinion that thunder is not heard farther than about twelve miles, but this distance may frequently be doubled at night, and sometimes tripled.

The maps show six areas of maximum frequency of thunder, Madagascar, Central Brazil, Panama, Southern Mexico, Central Africa, and Java, in which island thunder occurs on 61 per cent. of all days. Areas with thunder on less than 1 per cent. of all days are Greenland, north Iceland, north Norway, the north coast of North America, the Arctic Ocean, and the Antarctic Continent. There are areas of low frequency on the west coasts of North and of South America, and on the west coasts of South and North Africa; the latter area extends across the Sahara into Arabia, the other three do not extend far inland, but all of them go a long way out into the ocean. All these regions are on the east side of anticyclonic areas in positions where winds from a polar direction keep the surface temperature cool; they are also in regions of cool ocean currents, and, though Mr. Brooks does not actually point it out, these may have something to do with the low thunderstorm frequency; the Peru, the Benguela, the California, the Canaries, and the Labrador currents are all reflected in the isobronts; even the small cool current down the Korean coast shows its effect.

A very interesting map is given showing what percentage of thunder occurs in winter in western Europe; the 30 per cent. line extends down the Norwegian coast, embraces practically the whole of the British Isles, and crosses Brittany and the north-west coast of Spain, eastward the percentage decreases, but north-westward it increases to 75 per cent. for the region of Iceland and the Faroes. Another map illustrates the distribution of thunder over central Europe in July, and shows that the "chief maximum of thunderstorm frequency in Europe extends in a long narrow belt at the base of the northern slopes of the Alps."

It is estimated that over the whole globe 16,000,000 thunderstorms occur per annum, if the average duration is one hour, there are 1800 storms occurring at any one time, if there are approximately 200 flashes per hour in a severe temperate, or an average

¹ Air Ministry Meteorological Office Geophysical Memoirs, No. 24. The Distribution of Thunderstorms over the Globe. By C. E. P. Brooks (M.O. 254d) Pp. 145-164+4 plates (London H.M. Stationery Office, 1925) 2s. net.

tropical storm, there will be 100 flashes per second over the globe. The number thus estimated by Mr. Brooks is of the same order as the frequency of atmospherics, which may all, therefore, be possibly due to lightning. In further sections are discussed the variation of thunder with season and with latitude over both land and sea, the diurnal variation and the effect of height on thunder frequency.

Mr. Brooks's work is a most important addition to the literature of the subject, and is one that no meteorologist can afford to be without; it will also be of value to those who take an interest in thunderstorms without being themselves meteorologists.

Dr. Sen² has collected the records on wind components that have been published in the *Geophysical Journal*, and his paper is illustrated by tables and diagrams. The south-north and west-east components of the wind are discussed in relation to the annual and diurnal variation; maps show the averages of the gradient, the gradient wind, and the resultant wind for each month, and the growth of convection winds in summer—land and sea breezes—is investigated.

The scope of Mr. E. V. Newnham's work³ is best explained by the opening paragraph. "The object of this classification is to provide a ready means for discovering whether the conditions prevailing over the North Atlantic and Europe at any time bear any resemblance to situations that have arisen in the past at about the same time of the year, and, further, to bring into evidence any distributions of pressure which tend to recur and may be regarded as genuine types, and to determine the seasonal variations of such types." The position of anticyclones is the basis of the classification; the region between latitudes 30° N. and 80° N., and longitudes 30° E. and 70° W., has been divided into ten areas to each of which a letter has been assigned, the position of anticyclones is shown by the capital letters of the areas over which they occur, while the position of depressions is shown by small letters.

The work must have involved an immense amount of labour; Table III gives each of the 5478 days of the period concerned with the pressure distribution found on each, while Table IV gives an index of the pressure distributions with the dates on which each occurred. It will prove of great assistance to those who are interested in investigating types of weather and changes in types, the summaries are in an extremely convenient form for reference.

The International Psycho-Analytical Congress.

(FROM A CORRESPONDENT)

THE ninth international Psycho-Analytical Congress which assembled on September 3-5 at Bad Homburg, Germany, was marked by some interesting features. Unlike its predecessor which met at Salzburg at Easter 1924, under the shadow of Prof. Freud's serious illness, the ninth congress was very happily able to begin its business by sending Prof. Freud a congratulatory telegram on his restoration to health.

As at the last three congresses, dating from 1920,

the year which saw the first re-assembly since the pre-War period, many nations were represented, and by many distinguished names. In his presidential address, Dr. Karl Abraham, Director of the Berlin Psycho-Analytical Clinic, welcomed representatives, who with relatives and visitors numbered about two hundred, from Austria, France, Germany, Great Britain, Holland, Hungary, India, Poland, Switzerland, Russia, and the United States. Dr. Abraham expressed particular satisfaction at

the presence of his American colleagues, who included such well-known workers as Dr. Jelliffe and Dr. Pierce Clark of New York, Dr. Trigant Burrow of Baltimore, and Dr. Isidor Coriat of Boston. The attendance of representatives from France was another sign of the acceptance of Freud's views in countries which have hitherto stood aside.

The most important features to be noted in the movement are the developments of psycho-analytical theory and practice; the increase in the number of constituent societies, and in the membership of these societies, the continuous research work and the increased publication of results; the large amount of clinical work carried on, and the greater general attention given, even if at times in the form of opposition, to Freud's discoveries. The work of the Berlin and Vienna Polyclinics clearly evidences the need for, and appreciation of, psycho-analytic treatment, and it is much to be hoped that before long every country will establish similar clinics, especially so great and important a country as England, which is still, strange to say, without a solitary clinic for this treatment. The valuable help which can be obtained by those sufferers who have found no solution for their difficulties through existing methods of treatment will then be more widely appreciated.

The contributions to the Congress were divided into four sections: theoretical questions, therapeutical questions, clinical matters, and applied psycho-analysis—an arrangement which made for clearness and simplification. Perhaps the sections of the greatest interest, at least to the Congress as a whole, were the two dealing respectively with therapeutical questions and applied psycho-analysis. In the first section, Prof. Freud's paper, a very technical one, on "The Bearing of the Anatomical Differences in Male and Female on the Oedipus Situation," was read by his daughter, Fräulein Anna Freud, who is herself a brilliant children's analyst, practising in Vienna.

Great interest was shown in the paper given by Dr. Ferenczi (Budapest Psycho-Analytical Society), one of the most widely known Continental analysts, on "Counter-indications to Active Psycho-Analytic Technique," in which he dealt with the theme of "active therapy" once more. This subject, which was put forward by him at the Salzburg Congress and created a somewhat sensational effect as a seeming sharp departure from the Freudian technique in treatment, was now dealt with by Dr. Ferenczi for the purpose of pointing out certain misconceptions which had arisen. It was important, he said, to realise that he did not suggest the employment of this "active" technique for all cases under treatment or as the sole method in any individual case, or with rigorous application, but only as *one* method at given times and at an appropriate stage. In respect to his "terminal limit" for the patient's treatment and the complete severance between patient and analyst when such a limit had been reached, a view also put before the Salzburg Congress, Dr. Ferenczi explained that he no longer wished to adhere strictly to such practices, but rather to make use of them only in exceptional situations. It may be said that the general tenor of the paper was in the direction of more elasticity, more modification of previous stringent views, although without any abandonment of basic Freudian principles.

Much the same attitude was expressed in the paper given, in the same section, by Dr. Otto Rank (Vienna Psycho-Analytical Society) on the birth theory formulated by him at the Salzburg Congress, and embodied in his book, "The Trauma of Birth."

He made something of an apologia for his too definite pronouncement of a year ago, making it plain that he no longer regarded the birth-situation (the first great trauma) as the only significant one in the shaping of the individual's destiny, but as playing a vitally important rôle in the whole psychic drama. In this same section, two more papers of interest were Dr. Alexander's (Berlin Psycho-Analytical Society) on "Neurose und Gesamtpersönlichkeit," and Dr. Pierce Clark's (New York Psycho-Analytical Society) on "The Phantasy Method of analysing Narcissistic Neuroses."

In the fourth section, dealing with applied psycho-analysis, a brilliant paper evidencing deep research, was read by Dr. Géza Róheim (Budapest Psycho-Analytical Society), the well-known Hungarian anthropologist, who, it is interesting to recall, will read a paper before the Royal Anthropological Institute in London next month. Dr. Róheim took for his subject "The Scapegoat," and expounded the origin and significance of the idea of the sin-offering and expurgation among ancient and primitive peoples. Dr. Theodore Reik (Vienna Psycho-Analytical Society) gave a paper on "The Origin of Psychology," in which he dealt in a masterly manner with the problem of (to give a free translation of the German title) "How do Human Beings come to bother about Psychology?"

Dr. M. D. Eder (British Psycho-Analytical Society) gave a paper on a hitherto little-investigated subject, "A Contribution to the Psychology of Snobbishness," claiming it as appropriate that this theme should be dealt with by a speaker from England, since that country was the classic home of snobbery. He worked out in a very interesting manner the sources and significance of snobbishness, illustrated from actual analytical cases and from the rich material in English literature, especially the work of Thackeray ("The Book of Snobs," "Pendennis"), of Meredith ("Evan Harrington"), and of Thomas Hardy ("A Pair of Blue Eyes").

At the business meeting which concluded the Congress, after re-electing to another term of office the president, Dr. Karl Abraham, and the secretary, Dr. Max Eitingon, to both of whom the Congress expressed sincere gratitude for their past work, an important decision was taken. This was to form an International Commission, constituted from Committees formed in all the individual branch societies, to draw up regulations acceptable to all countries represented in the Association for the admission of practising analysts. For some time past it has been felt that the qualifications demanded from practising analysts differ too widely according to the country concerned and even the individual psycho-analytical society. In some cases the regulations are exceedingly strict, making for assured scientific equipment; in other cases, however, the qualifications demanded are too slight to ensure any genuine knowledge or experience on the part of the so-called analyst, or even that he has subjected himself to a real analysis. It is hoped that the new Commission will be able to frame regulations sufficiently acceptable to create uniformity of qualification, which shall be such as to ensure a high standard in respect of knowledge, training, and personal suitability for psycho-analytic practice.

The business proceedings ended with a debate on the meeting-place for the next Congress. The final choice lay between Italy and England, an invitation to the latter being extended by Dr. Ernest Jones, president of the British Psycho-Analytical Society, and predecessor of Dr. Abraham as president of the International Association. The question of distance

was of importance to the Continental members, and ultimately, by a very small majority, Italy was selected.

In conclusion it is interesting to note that the characteristic feature of this Congress, one that sharply differentiated it from its predecessor, was the absence of dogmatic pronouncement and rigid conception, rather there was an apparent desire to discover how new, or partially new, theories could

be adjusted to already established facts, and a spirit of modification and adaptation on the part of those who earlier had put forward ideas of a somewhat disruptive nature. This attitude, with the important decision already referred to in the direction of uniformity and increased efficiency in psycho-analytic practice, augurs hopefully for future developments in psycho-analysis, both in research and practical therapeutic work.

The Royal Photographic Society's Exhibition.

THE annual exhibition of the Royal Photographic Society at 35 Russell Square, London, W.C.1, remains open until October 24, and admission is free. The scientific and technical sections are numerous, and each contains exhibits of notable interest. The Astronomer-Royal shows "Prism-crossed Grating" spectra of Vega compared with spectra of the carbon arc and a 3-watt electric lamp. The comparison of these spectra gives data from which the temperature of the star may be calculated from the known temperatures of the artificial illuminants. Star spectra enlarged 7.6 times horizontally and broadened 19.5 times by means of a clepsidra apparatus invented by the exhibitor are contributed by Dr W. J. S. Lockyer. Among the aerial photographs are several fine examples by the Royal Aircraft Establishment, and the application of this method of work to archaeological research is well illustrated by Messrs O. G. S. Crawford and A. Keiller, one of whose examples reveals an ancient village site seen through the crops, in Hampshire.

The natural history section is a very large one, and those of the ordinary kind are only mentioned as a group because there is such a great variety of good work. But Mr Oliver G. Pike has endeavoured, with success, to show the action of the wings of birds during certain phases of flight. Presumably these photographs are enlargements from his slow motion cinematograph films shown elsewhere. Among the specimens of cinematograph films are some from the Eastman Kodak Research Laboratory which illustrate some possibilities in the use of colour and form in motion as a means of entertainment and to produce pleasurable sensations by an appeal to the visual sense similar to those produced by music. The kodachrome two-colour subtractive process is used in the production of these films.

The photomicrographs are many and chiefly low power work. Dr G. H. Rodman illustrates the structure of the petiole of the water hyacinth, an aquatic floating plant of tropical America. In another series of 24 sections he shows the character

of the idioblasts which occur in various water lilies. Mr F. Martin Duncan contributes further studies on the cuticular scales of mammalian hairs, which confirm his theory of the importance of their specific characters in the phylogenetic study of mammals. Photomicrographs of several alloys, chiefly alloys of copper, and illustrating flaws and changes produced by various treatments, are contributed by Capt J. W. Bampfylde. Micro-radiography as applied to geology and palaeontology is illustrated by 24 examples by Pierre Goby, who also has four stereo-micro-radiographic pairs showing stereoscopic relief and pseudo-relief. Of natural size radiographs there are many examples.

Among the other examples of the application of photography to scientific investigations may be mentioned shutter test diagrams with full explanations from the optic division of the National Physical Laboratory, and Prof Coker's natural colour transparencies which show the nature of stress under various conditions in models of buildings. The transmission of photographs over telephone wires for practically any distance and in a few minutes is illustrated by the International Western Electric Co., which shows transmitted photographic portraits, landscapes, views of buildings, letterpress, a fingerprint, writing, charts, and a coloured photograph. The perfection of the reproductions is remarkable. Mr Thorne Baker has an example of a picture transmitted by wireless telegraphy. The British Photographic Research Association shows the effect that fuming with ammonia has upon the character of the grain of silver bromide gelatine plates. The selenium density meter designed by members of this Association is shown by Watson and Sons, and in the rather large trade section Chance Brothers show optical glass from its manufacture to the finished lens, and specimens which illustrate the effects of tests for durability, of devitrification, and of the improvements in the quality of dense barium crowns in the years 1915, 1917, 1924, and this year. In the last the colour is practically eliminated and bubbles are scarcely visible.

Oyster Dredging in the Fal Estuary.¹

DR J. H. ORTON, of the Marine Biological Association, presents a useful report on the oyster fisheries of the Fal Estuary, which are managed by the Truro and Falmouth Corporations, being owned by the Duchy of Cornwall. Each dredgerman takes out a licence and is entitled to dredge oysters more than 2½ inches in diameter during the winter months. The proceeds formerly were largely used up in lawsuits, but we judge that they now mainly pay the wages of bailiffs, whose business it is to see that the size regulation is observed. There would seem to be no cultivation of the oysters, no cleaning

of the grounds, no laying of suitable hard material on which the spat can settle (cultch), nothing indeed beyond the relaying of already marketable oysters in private or leased intertidal waters until there are suitable market conditions.

The spat falls in the three years 1922-24 were failures, and, as oysters are usually caught for market in their fourth and fifth years, the fishery is bound to be too lean for most of the 200-300 dredgermen to obtain a livelihood in 1926-29, even if the present year should see a good spat fall. Dr. Orton does not deal with the causes of the bad spat fall, and it is not clear whether there was an insufficiency of oyster larvae, or whether the ground was so muddy that they could not survive when they settled on the bottom.

¹ Summary of a Report on a Survey of the Oyster Beds in the Fal Estuary in November 1924, with Notes on the Biology of the Oyster. By Dr J. H. Orton. (Published for the Falmouth and Truro Corporations.)

We suspect the latter, as so much stress is laid on cultching as compared with the establishment of proper spawning stocks. Further, the small, misshapen, nut-like, rounded oysters, forming 45 per cent. of the stock, are characteristic of dirty ground.

The total stock on the grounds is estimated at about 8 millions, sufficient, if the "nuts" be deducted, to give a catch of upwards of a million a year, while in the last century the average catch was many times as much. Of course, the raising of the catchable size and all sorts of restrictions in the fishing are suggested, but it is questionable, if Dr. Orton's facts be accepted, whether these could do more than keep a limited number of dredgers on the grounds while administrative authorities are seeing whether they will do anything.

Dr. Orton's summary does not tell us the exact condition of the Estuary to-day, but in 1915 the shores and main channel were filthy with mud, detritus, weed, etc., and the real question then seemed to us to be whether money could be found to harrow and cultch selected areas and afterwards to keep them in good order. A careful study of the alterations in land drainage, in mine workings, etc., of the watershed of the Estuary during the last century should show whether this is worth doing at all, and, if it be done, all regulations should be re-examined so that the fishermen should act as their own bailiffs for the new regulations, while their licence fees or royalties would be available for the upkeep of the whole grounds. We feel that it would be best for the two Corporations concerned either to return the fisheries to their owner, or to place themselves in the hands of Dr. Orton, or some other competent person, and carry out his behests.

J. S. G.

University and Educational Intelligence.

ST. ANDREWS—Dr. David Rutherford Dow has been appointed to succeed Principal Mackay in the chair of anatomy in University College, Dundee. Since 1913 Prof. Dow has been lecturer in regional anatomy at the United College and assistant successively to Prof. Musgrove and Prof. Waterston, the Bute professors of anatomy there. His research work in anatomy has resulted in several papers published in the *British Medical Journal* and the *Journal of Anatomy*.

THE East Anglian Institute of Agriculture, Chelmsford, gives details in its Calendar for 1925-26 of some eighty courses which it offers in its departments of agriculture, agricultural biology, agricultural chemistry, dairy technology, horticulture, and poultry and small live stock. It undertakes to prepare students not only for its own certificates and diplomas and those of the Royal Agricultural and Royal Horticultural Societies and the British Dairy Farmers' Association, but also, in conjunction with University College, London, Bedford College for Women, East London College, and Chelsea Polytechnic, for the degrees in agriculture and horticulture of the University of London. The Institute specialises in animal husbandry, and farm economics, dominion agriculture, dairying, and commercial horticulture. It conducts a school gardening class on Saturdays for teachers. The North of Scotland College of Agriculture offers courses for the university degree in agriculture, the national diplomas in agriculture and dairying, a college diploma in poultry-keeping, and a special farmers' course in the winter. A joint committee of the College and the University of Aberdeen controls the Rowett Institute for Research in Animal Nutrition.

Societies and Academies.

WASHINGTON, D C

National Academy of Sciences (Proc Vol 11, No 8, August)—**Edwin B Wilson**. The logistic or autocatalytic grid. Arithmetic and logarithmic probability paper, on which the integrals of certain curves become straight lines, is of value in problems in chemistry, biology, economy and other subjects.—**Nelson W. Taylor and Gilbert N. Lewis**. The paramagnetism of "odd molecules". Evidence of paramagnetism was obtained for chlorine dioxide (in carbon tetrachloride), the free organic radical α -naphthyl diphenylmethyl (in benzene) and in solutions of sodium in liquid ammonia and of thallium in mercury. In the latter solutions an electron is given up by the dissolved metal to the solvent, thus forming a molecule (the solvent) containing an unpaired electron.—**Allan C. G. Mitchell**. The activation of hydrogen by excited mercury atoms. The rate of reaction of mixtures of hydrogen and oxygen in the presence of mercury and exposed to light from a mercury lamp was measured and the effect of addition of argon determined. As the pressure of argon is increased, the reaction-rate decreases.—**Selman A. Waksman**. What is humus? 60-70 per cent. of the organic matter in the soil, including the "humic acids," is soluble in alkalis and precipitated by acids. This portion can be divided into α - and β -fractions which are insoluble and soluble respectively in dilute acids. The α -fraction (or "humic acid") gives the soil its black colour and is derived from lignins and the cells of soil micro-organisms. The β -fraction provides the buffering properties to soils. Peat soils contain largely the α -fraction, while mineral soils contain the β -fraction in addition and often predominating.—**R. L. Moore**. Concerning the separation of point sets by curves.—**Selman A. Waksman**. The soil population. Soil organisms form a biological complex and should be studied as such.—**Ludvig Hektoen and Kamil Schulhof**. The precipitin reaction of thyroglobulin.—**J. B. Collip**. The internal secretion of the parathyroid glands. The secretion can be obtained in a stable form and in a degree of purity and potency hitherto not available. The method used is the dissolution of gland by controlled acid hydrolysis and isoelectric fractionation. The hormone obtained is specific for parathyroid tetany in dogs; its effect is related in the main to calcium metabolism and it causes mobilisation of calcium in the blood.—**Samuel K. Allison and William Duane**. An experimental determination of the critical excitation frequency for the production of fluorescent X-radiation. It would appear that to produce a fluorescent line spectrum, the primary radiation must contain X-rays of frequency at least as great as that of the corresponding critical absorption.—**William Duane**. The calculation of the X-ray diffracting power at points in a crystal. To calculate the density of the diffracting power (or density of electron distribution) from the measured intensities of diffracted beams, certain fundamental assumptions relating to the symmetry of the crystal must be made.—**Carl Barus**. The effect of commutation of impedances on the acoustic pressure produced by paired telephonic systems.—**R. T. Cox and J. C. Hubbard**. A statistical quantum theory of regular reflection and refraction. Large aggregates of quanta are dealt with, and it is assumed that the media traversed by these quanta are continuous, that the quanta travel with the velocity of light and suffer a change of velocity but not of energy on passing from one medium to another.—**R. J. Havighurst**. (1) The distribution of diffracting power in sodium

chloride. The density of electron distribution indicates that along the cube edge and body diagonal there is an alternation of two kinds of atoms; along the face diagonal, all are alike. (2) The distribution of diffracting power in certain crystals. Potassium and ammonium iodide have the sodium chloride structure; ammonium chloride has the body-centred caesium chloride structure. The "electron density" of diamond cannot yet be determined.—A Keith Brewer: Ionisation produced in gaseous reactions. Ethyl alcohol and oxygen are allowed to react, at temperatures below that of ignition, between gold, aluminium, copper, and glass electrodes. It is concluded that ions are formed in the gas layer in immediate contact with the electrode and that positive and negative ions are formed in equal numbers.—G. F. Rouse and G. W. Giddings: Ionisation of mercury vapour by ultra-violet light. When mercury vapour between two plane parallel electrodes is illuminated by light from a hot mercury arc, the ratio of the currents to the two electrodes is approximately that of the areas of the electrodes, indicating photo-electric action. With a water-cooled mercury arc and increased mercury vapour pressure, the currents observed are much greater and their ratio practically unity, indicating true ionisation. No single wave-length of sufficient energy to do this appears to be present, so a cumulative action must occur.—O. K. De Foe and G. E. M. Jauncey: Modified and unmodified scattering coefficients of X-rays in matter. Taking into consideration Compton's change of wave-length with scattering, the ratio of the scattering coefficient of the modified to the unmodified rays is calculated. Experimental results using copper are in fair accord with the calculation.—G. E. M. Jauncey and O. K. De Foe: The energy reappearing as characteristic X-rays when X-rays are absorbed in copper. The methods developed in the previous paper are used, and it is found that the greater part of the energy absorbed goes into the photo-electric ejection of K-electrons.

SYDNEY.

Royal Society of New South Wales, August 5.—G. Taylor, W. R. Browne, and F. Jardine: The Kosciusko Plateau, a topographic reconnaissance. The area investigated extends from "The Créal" at 3000 feet elevation in the east, to Kosciusko (7300 feet) in the west, a distance of 20 miles. As a result approximate contours (form-lines) of 100 feet interval were obtained, and these have been drafted on a map to the scale of half-mile to the inch. Aneroid and Abney-level observations were relied upon for heights. These were supplemented by sketches and photographs which were carefully orientated and annotated.—A. R. Penfold and J. L. Simonsen: The essential oils from the leaves of *Murraya Koenigii* (Spreng), *Murraya exotica* (Linn.), and *Murraya exotica*, var. *ovatifoliolata* (Engler).—J. H. Maiden and W. F. Blakely: Descriptions of sixteen new species of Eucalyptus. Six are eastern species (including one from South Australia) and ten from Western Australia. Two are suggested hybrids, while one has already been described as a variety. Of the eastern species, three are from Queensland, a pale-wooded bloodwood, a northern box and a glaucous ironbark, also from the north. Of the two suggested hybrids, the South Australian one comes nearest to *viminialis*, while one from the Federal Territory is a rough-barked species nearest to *maculosa*. The western species include five mallees, and two fairly large trees, the "Stocking tree" of Kondinin, so called because of its rough bark, sharply defined from a smooth trunk, and the Albany blackbutt, raised to specific rank.

Research on Foot-and-Mouth Disease.

SINCE Loeffler and Frosch in 1897 reported the striking fact that the fluid from the vesicles which form the main outward lesion of foot-and-mouth disease in bovines, could, after dilution with water, be passed through kieselguhr filters without suffering loss of potency, it has been customary to regard the virus of this, perhaps the most contagious of all animal diseases, as belonging to the group of ultra-visible or filter-passing viruses. This demonstration by Loeffler and Frosch was, indeed, the first indication that an animal disease might be associated with a virus the minute size of which permitted it to pass with ease through filters which retained the ordinary microscopic bacterial forms.

On the Continent, especially in France, Germany, and Holland, where foot-and-mouth disease has long maintained a strong foothold, experimental research has been very intensely and continuously prosecuted, largely with a view towards the elaboration of specific methods of prevention and cure. Though much information with regard to the properties of the virus emerged from these investigations, it cannot be said that any decisive solution of the problem of prophylaxis was reached which would be applicable, at any rate, to a country such as Great Britain, which is liable only to occasional outbreaks readily controlled, as a rule, by wholesale slaughter of affected animals and contacts. Further, the accumulated research data have been to some extent of uncertain quality, probably because of the expense involved in carrying out experiments on bovines on a sufficiently grand scale. It came, therefore, as something of a surprise when Waldmann and Pape in 1920 showed that guinea-pigs could be infected with the virus of foot-and-mouth disease. Loeffler's earlier results in this connexion had been negative and the non-susceptibility of small animals had long been regarded as a *chase jugée*.

The new knowledge, as might have been expected, immediately opened up a new and readily exploitable field for further experimental investigations of the foot-and-mouth virus. In April 1924, Frosch and Dahmen, working in Berlin, announced that they had succeeded in cultivating the virus through many generations on an artificial medium and that by a photographic process they had been able to render the virus visible.

It was at this juncture that the Ministry of Agriculture in Great Britain, faced with the severe and continuing prevalence of foot-and-mouth disease in the country, took the enlightened step of appointing a research committee of ten medical and veterinary experts, with Sir William Leishman as chairman, "to initiate, direct and conduct investigations into Foot and Mouth disease either in this country or elsewhere,

with a view to discovering means whereby the invasions of the disease may be rendered less harmful to agriculture." The first progress report¹ of this research committee has just appeared. It contains no dramatic discoveries, but there is abundant evidence of carefully conducted work leading to decisive conclusions in regard to many hitherto obscure points connected with the properties of the foot-and-mouth virus. So far, the research has been conducted in two establishments, at the Lister Institute, where several workers specially engaged by the committee are being directed by Dr. J. A. Arkwright, a member of the committee, and at the Ministry's laboratories at New Haw, Weybridge, where the work is under the immediate supervision of Sir Stewart Stockman.

Both groups have been working on very similar lines, and both have been employing the guinea-pig as the test animal with great success. The method of choice for inoculating this animal with the foot-and-mouth virus is the intracutaneous, in the hairless pads of the hind feet. In twenty to twenty-four hours redness and swelling at the site of inoculation give place to extensive formation of vesicles locally, and this is followed by generalisation of the virus throughout the body, as evidenced by the presence of minute vesicles in the fore feet and tongue and by the infectivity of the blood. The energies of the workers were devoted in the first instance to traversing the claims of Frösch and Dahmen, but with the exception of one or two results of dubious interpretation, no confirmation whatever of the claims of the German workers was obtained. In Germany also, Frösch and Dahmen's claims do not appear to have received any acceptance. It has been apparent, in fact, that the virus tends to die out rapidly, in a matter of hours, when kept at 37° C. on a variety of artificial media. Low temperatures, on the other hand, have favoured its survival.

Always, therefore, with the view of ultimate successful culture, efforts have been concentrated on testing the most suitable conditions for survival of the virus at a temperature of 37° C., and it has been found, for example, that in phosphate solution of pH 7.6 the virus can remain active for four or five days at 37° C. The virus shows a surprisingly high resistance to chloroform and alcohol. In 60 per cent. alcohol, for example, it preserves its potency for eighteen hours at room temperature, while organisms like *B. coli* and *S. pyogenes aureus* are killed in one minute under the same conditions.

Many attempts have been made to infect with the virus other small animals such as rats and mice. Accurate knowledge on this point was desirable, in

view of the obscurity that not infrequently surrounds the paths of dissemination of foot-and-mouth disease. White rats, wild rats, white mice, and house mice only very occasionally give evidence of susceptibility to experimental inoculation. On the other hand, the long-tailed field mouse (*Apodemus sylvaticus*), twelve of which were tested, could be infected with ease. No evidence has emerged, however, to show that, either under laboratory or field conditions, foot-and-mouth disease can spread among these small animals.

Recently the Cattle Testing Station at Pirbright has been adapted for experimental work with cattle, sheep, and pigs, every precaution being taken to prevent the entrance or escape of infection. At this station, only, will such experiments be permitted. While research on foot-and-mouth virus with the guinea-pig as test animal is proceeding at approved institutes, the new experimental station will prove a most valuable adjunct for the final testing of varied material on bovines.

The People of Europe.

Racial Realities in Europe. By Dr. Lothrop Stoddard.

Pp. v+252+3 maps. (London: C. Scribner's Sons, 1924.) 12s. 6d. net.

READERS of Dr. Stoddard's "Rising Tide of Color" or his "Revolt against Civilisation" will know what to expect of the essay at present under notice. "More and more we are coming to realise the fundamental importance of race in human affairs" (p. 3); and the superficial similarity of the civilisation of European countries should not obscure the racial differences between their populations. Climate and soil may account for much, but "are not so universal in their effects as race, which subtly but inevitably influences every phase of human existence" (p. 5). Since on Dr. Stoddard's race-map, accepted without change from Madison Grant's "Passing of the Great Race," "we see a Europe inhabited by three races [Nordic, Alpine, and Mediterranean], Europe's seemingly tangled history grows much simpler, while present-day conditions become more understandable" (p. 5): especially as "Europe is a striking example of the persistence of race" (p. 8), and "even in those regions where racial mixture has been most prolonged and general we find populations not fused into new intermediate varieties with harmonious, stably blended qualities but composed of obviously mixed individuals"—a rather ambiguous phrase—"most of whom can be classified as belonging mainly to one or other of the ancestral types" (p. 9). The reason given for this is "another law of races—the tendency to breed out alien strains when these are not too numerous, so that such strains ultimately vanish, and never reappear in the stock." It is argued

¹ First Progress Report of the Foot-and-Mouth Disease Research Committee. Ministry of Agriculture and Fisheries. (London: H.M. Stationery Office, 1925.) 1s. 3d. net.

that since "these three races differ markedly from one another, not merely in physical appearance, but also in intellectual and emotional qualities" (p. 6), circumstances such as war or industrialism, less favourable to one race, or more so to another, produce the profound social effects which we know, by altering the racial composition of the peoples exposed to them; and the citizens and statesmen momentarily concerned with understanding and alleviating the troubles that ensue, are warned to take account of these anthropological factors, and will disregard them at their peril.

So long as the argument remains in general terms of this kind, it may claim general concurrence. It is only when this kind of applied anthropology begins to be applied to particular cases, that difficulties and objections occur. Even if it be granted that "practically pure-blooded Alpines" are really to be found, for example (as Dr. Stoddard says, p. 15, cf. 170) in "the early Russians" and "the other Slav tribes," do the "Alpine qualities of tenacity, instructive solidarity, and dogged endurance," that "very passiveness" which "has helped to give them the ultimate victory," quite explain the process by which the Slav peoples imposed themselves on the large areas of eastern Europe during their historic periods of migration? And were the "early Russians" or any other Slavs "practically pure-blooded Alpines" at all, when they entered those regions? And if they were, how does Dr. Stoddard know this? Ripley, whose racial theories Dr. Stoddard follows in the main, says that the Alpine type "becomes less pure in proportion as we go east from the Carpathians across the great plains of European Russia" ("Races of Europe," p. 128). In the same way, is it through the "instinctive solidarity" or the "very passiveness" of Alpine temperament that "the Balkan peoples, who are of course mainly Alpines, are always quarrelling and fighting among themselves" (p. 15); and further, in what sense are the Bulgarians "mainly Alpine," or were their Finnish ancestors from far up the Volga themselves "mainly Alpine," and if so, once again, how does Dr. Stoddard know?

In spite of their "tenacity, instinctive solidarity," and so forth, Dr. Stoddard does not wholly approve of "Alpines"; at all events he says (p. 16) that this race "has contributed little that is truly great to politics, art, or ideas," and that "the total absence of Alpine blood in the British Isles is undoubtedly one of the chief reasons for the high qualities of its inhabitants." It is comforting to be assured of our high qualities, still more to learn that there is such a simple reason for them—though it is to be hoped that no British reader of "Racial Realities" will so far practise applied anthropology as to knock on the head as an alien enemy the next Alpine he meets. But, once

again, how does Dr. Stoddard know? Still more surprising, though no less complimentary to ourselves, is his insistence on our "predominantly Nordic" quality, and his association of Scotland with England in this respect, in contrast with Wales and Ireland. If "Nordic" in this context means the same thing as in the chapter on the "Nordic North," described as making Scandinavia "to-day the brightest spot on the Continent of Europe," does it mean a group of mental qualities, or a homogeneous physical type? Unless it means both of these, what becomes of Dr. Stoddard's thesis of the coherence of physical types with mental qualities? Even in Sweden there are only about 54 per cent of pure blonds.

The truth is, that the three-race theory of European ethnology, popularised both in Britain and in the United States by Ripley's brilliant "Races of Europe" some twenty-five years ago, needs a good deal of supplement and qualification before it can be applied to modern nationalities in the way Dr. Stoddard and other recent writers, mostly American, propose. Not only has there been, as Ripley himself frankly admitted, a great deal of interbreeding—so that "in the greater number of cases no invariable association of traits occurs" ("Races of Europe," p. 105), but a chaos of dysharmony—but this interbreeding has in all probability gone so far as to permit the establishment of well-defined secondary types; the so-called "prospectors" along ancient zones of contact between Alpine and Mediterranean populations, and their northern counterparts, the "beaker-folk," as interpreted for example by Sir Arthur Keith, along the margin between Alpine and Nordic areas. There is also cumulative evidence of the persistence of very ancient strains, linking the men of the Plynlimmon moorland with Aurignacian man, the early inhabitants of the Upper Danube basin with peninsular Italy, and so forth, in a fashion which complicates the interpretation of all brunet-longheaded "races." It has also to be remembered that all the three "great races" are themselves abstractions and generalisations from observed coherences or associations of a few easily recognisable characters—headform, pigmentation, and the like—which are observed, however, in infinitely varying degrees in a vast number of individuals. Among Alpines, for example, and in respect of headform alone, there is marked difference between the Cevenole, the Tyrolese, the Albanian, and the Armenoid types, and some reason already to believe that concurrent processes of differentiation and dispersal are recognisable, around a geographical centre in the Near East, which may turn out to be a cradle historically.

What has to be remembered, in the writings of Dr. Stoddard, Madison Grant, and others, is that, as so often

in the past, anthropology has had its opportunities made for it by the political situation. Some of us can remember Max Müller's contributions to the literature of the Russo-Turkish War of 1878, some even the controversy opened by de Quatrefages in his pamphlet "La Race Prussienne." A more recent example is Houston Chamberlain's version of the "racial realities" of Europe - before - the - War. Latterly, the practical difficulties of Americanising large masses of immigrants, from southern and eastern Europe, have led to desperate remedies, and the need to justify them before both American opinion and that of European countries; and this emergency, like all such, has come at a particular phase of anthropological discovery and ethnological theory. But between the canny criticisms of modern European temperaments and predicaments, which are the really interesting part of Dr. Stoddard's book, and the theoretical explanation which he offers us in his diagram of European race-distribution, there are weak links. The kingdom of truth suffereth violence, and the violent take it by force. Over-simplified as it is, Dr. Stoddard's masterkey is a skeleton key; if it turns the bolt, it is not by fitting the wards.

J. L. M.

The Investigation of Colour-Vision.

Colour-Blindness. with a Comparison of Different Methods of Testing Colour-Blindness. By Dr. Mary Collins. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xxxi + 237. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1925.) 12s. 6d. net

THAT theories are useful servants but bad masters is borne out by a study of this book. It embodies "the results of research on red-green colour-blind subjects," and "the tests were carried out unbiased by any preconceived theory and no rigid classification was attempted during the experiments themselves." A mass of observations on ten excellent subjects, eight being students attending the graduating course in experimental psychology, and two science students, has been accumulated. All will admit that such material is of great value, but that alone it is unlikely to afford an explanation of the complex problem under investigation. Its ultimate value will depend upon the deductions drawn from it, and these must necessarily involve theoretical considerations which may support or be adverse to previous theories. In this respect it is essential that the investigator should be fully cognisant of the facts which have been elicited by previous observers, whether they support any such theory or not.

The author states that, "as the facts accumulated, the explanation stood out clearly that the subjects were not all suffering from total blindness to red and green, and that in their inability to discern these colours they could be graded as in a scale." Further, "one other interesting result which emerged from the tests was the indication of the existence of two neutral bands—one in the blue-green region of the spectrum, the other beyond the spectrum in the complementary purple." On the first point Dr. Drever says, in the introduction, "This highly significant fact would seem to involve some modification of most existing colour theories"; on the second point, "Perhaps nothing could throw into clearer relief the inadequacy of a study of colour-blindness based on the spectrum, or the dangers lying in wait for the theorist who fails to distinguish between physical colour and physiological or psychological colour."

The reader could scarcely deduce from these remarks that both facts have long been well known. So long ago as 1895, Sir William Abney, in his Tyndall Lectures at the Royal Institution, demonstrated the "neutral band" in the purple. "The green, he calls white, as he also does the purple" ("Colour Vision," p. 71, 1895). *Pace* Dr. Drever, these are the observations of a physicist, who worked almost entirely with the pure spectrum. It is, in fact, an immediate deduction from the Young theory, for if the green appears white to the colour-blind person, it is obvious that its complementary purple must also appear white. Further, it should have been well known to the author and to Dr. Drever that Abney long ago actually measured the amounts of the deficiencies in terms of the Young theory in different observers (see especially Abney and Watson, *Proc. Roy. Soc., A*, 88, 410, 1913), thus fully recognising degrees of the defect.

The author's opening statement that "the study of colour-blindness has been somewhat retarded by the concomitant study of colour theories" is really astounding. It may be true that "the majority of investigators have started out unduly biased by their favourite theory, and have examined colour-blinds from this prejudiced standpoint," but it cannot be doubted that most of the facts of colour-blindness have been elicited by these observers, and that the contentions of the supporters of the Young and Hering theories acted as a great impetus to the study of the subject. It is true that the psychologically inaccurate nomenclature of adherents to the Young hypothesis, *e.g.* "red-blind," "green-blind," etc., has led to much confusion. Even so, let him who is without sin cast the first stone. We have no reliable knowledge whatever as to how a colour-blind person actually sees the colour of the spectrum; yet Dr. Drever, a psychologist, writes: "The red-green blind sees blues and yellows. Hence a yellowish-

red or a yellowish-green will be seen as yellow. . . Purples will be blue, if there is sufficient blue in them to be apprehended . . . The results obtained by Dr Collins enable us to form a fairly accurate idea of the colours of this world."

Dr. Drever says that "colour-vision is primarily the field of the psychologist," but natural phenomena are not divided into these water-tight compartments. Psychology, except as a mass of philosophical speculations, is based upon physiology, which itself is based on chemistry and physics. The psychologist who is not adequately equipped with knowledge of physics is even less likely to succeed in solving problems of colour-vision than the physicist. We agree that vision, including colour-vision, should be the particular study of psychologists, for upon vision more than upon any other sense the advance of the primates to man depended. Psychologists have contributed far less than physicists and physiologists to our present knowledge of colour-vision, and are likely to continue to do so until they realise that the approach to psychology must be from the biological rather than the philosophical side.

Historic British Scientific Instruments.

Historic Instruments for the Advancement of Science: a Handbook to the Oxford Collections prepared for the opening of the Lewis Evans Collection on May 5, 1925
By R T Gunther. Pp. iv+90. (London: Oxford University Press, 1925.) 2s 6d net.

FEW of those who use scientific instruments realise the important part which Great Britain has played in their development; although not written at all from this point of view, it is easy to see from Dr Gunther's book many examples of the contributions of the British makers and men of science. He points out, for example, that among nautical instruments, the backstaff, which was a great improvement on the fore-staff for the determination of the sun's altitude, was invented by an English captain, John Davis, in 1590, to avoid having to look directly at the sun; then there were the improved quadrants of Edmund Gunter of Oxford, and of Sisson, lastly, the reflecting octants of Newton and Hadley—the immediate predecessors of the modern sextant.

The theodolite, the chief surveying instrument, was the invention of Leonard Digges, of University College, Oxford, and was described by his son in 1571. The accurate dividing of a circle was carried out by Ramsden with his dividing engine in 1763, who thus led the way in the construction of surveying instruments of all kinds.

Of mathematical instruments, Dr. Gunther quotes Stone's remark in his translation of Bion (1758):

"The making of good mathematical instruments is almost peculiar to the English" Napier following his invention of logarithms, devised his "Bones" by which multiplication could be performed mechanically. Shortly after, Gunter (1620) made his "line" and Oughtred his "circle of proportion" (1630), from which the slide rule has descended.

Turning to the telescope, Gregory and Newton devised the reflecting telescopes called after them, and of much greater importance, the refracting telescope was suddenly brought from a clumsy and very defective instrument, a hundred or more feet in length, to an almost perfect instrument through the discovery of achromatism, first by Chester Moor Hall (in 1733), and then by the careful experiments of John Dolland in 1658; the telescopes Dolland made were for their size little inferior to those of the present day.

Lastly, the most important of all scientific instruments, the microscope, from the time of Hooke, who described and illustrated his famous instrument in his "Micrographia" in 1665 (the date 1667 mentioned by Dr. Gunther is the date of the second edition) down to nearly the end of last century, owes all the chief improvements to the British makers. The microscopes of Marshall, Culpepper, Cuff, Adams, Dolland, Nairne, are briefly referred to by Dr. Gunther.

In the Science Museum at South Kensington there is a fairly representative collection of scientific instruments if we include the portion of the fine collection of these old instruments formed by Thomas H. Court during the last thirty years, which has been on loan there so many years; but even including these there are many gaps, especially in the instruments produced during the latter end of the seventeenth and the early years of the eighteenth centuries—a most important period in the development of scientific instruments, as it was during this period that so many of the features that still persist were first introduced.

Oxford has in Dr. Gunther another man of enthusiasm, who seems determined to build up a representative collection there. He has been fortunate in starting with a nucleus of three unique collections—the Orrery collection, made by a grand-nephew of Hon. Robert Boyle c. 1700; the Oriel collection of instruments dated about a hundred years later, mostly constructed by Nairne; and the Lewis Evans collection, recently presented to Oxford.

Dr. Gunther has already published three finely illustrated volumes descriptive of some of the more interesting and important of the instruments, but these are necessarily expensive, while the little book that has now appeared is within the reach of all, and it gives in brief outline a general survey of the collection together with sufficient historic notes to place the instruments

in their true perspective, and to enable the general reader to form some appreciation of the interest and value of the collection.

The University of London has established a degree in the history of science, and it is possible that other universities will follow suit, if so, collections in which students can follow the development step by step will be necessary for any proper appreciation of the subject. As these old instruments—not so much the antiques which are probably safe, but the intermediate links—are being broken up every day by those ignorant of their importance, no time should be lost by other universities, especially the sister University of Cambridge, in forming a similar collection.

Introduction to Biology.

- (1) *Allgemeine Biologie: eine Einführung in die Lehre vom Leben.* Von Prof. Dr. Max Hartmann. Erster Teil: Zelle, Statik, Dynamik und Stoffwechsel. Pp. vi+262. (Jena: Gustav Fischer, 1925.) 12 gold marks.
- (2) *Outlines of General Zoology.* By Prof. H. H. Newman. Pp. xvi+480. (New York: The Macmillan Co., 1924.) 16s. net.
- (3) *A Text-Book of Biology for Students in General, Medical and Technical Courses.* By Prof. W. M. Smallwood. Fifth edition, thoroughly revised. Pp. 393. (London: Baillière, Tindall and Cox, 1925.) 16s. net.

NOT the least evident of the signs that biology is finding its place in a general education is the crop of books intended to introduce the student to it which is now appearing. Three such are before us.

(1) Prof. Max Hartmann publishes the first of two parts of a work founded on his lectures on general biology in the University of Berlin. This is in title and manner an introduction, it is true, but it is an introduction on an ample scale, and suited only to serious students. It is broadly and philosophically conceived, and worked out very systematically in the German way. Prof. Hartmann begins at the beginning. In an opening section he considers the philosophical prolegomena of the subject—the position of biology in the system of the natural sciences, the methodology of the biological sciences, and the scope of general biology.

In treating of methodology, Prof. Hartmann gives an interesting and very judicious exposition of the respective functions of generalising and exact induction, and of the part played by hypothesis and experiment in the development of the science. As might have been expected, he views general biology as primarily the study of cell life, and begins his exposition of its

principles with a survey of our knowledge of the cell. He draws the very necessary distinction between cell and energid, but unfortunately adheres to a use of the former term which compels him to apply it to the whole body of various organisms, from bacteria to *Caulerpa*, which are much better described as non-cellular. It is a pity thus to reduce to absurdity a conception which, rightly used, is of much value. Upon the question of "generative chromidia," which is briefly discussed in this section, the recent observations of Sister Monica Taylor on the life-history of *Amoeba* throw some further light. A survey of the various skeletal and formative structures of cells follows, and then a section upon various types of motion. Here some allusion to recent English and American work on amoeboid movement might perhaps have been made. Muscular contractility and the organs which subserve it are discussed in an excellent summary.

Part I. of the work ends with an admirable survey of the interchange of matter and energy between the organism and its surroundings, illustrated by an elaborate tabular statement. The style throughout is clear, and the illustrations plentiful and well printed. We are promised Part II., which will complete the book, in the course of next year.

(2) and (3) The other two books are ordinary enough examples of a common type—the introductory textbook for elementary students. Prof. Smallwood writes for students of biology, Prof. Newman for those who are studying zoology. Each states briefly a number of elementary facts and theories. Each at least avoids giving the impression that biology consists in a knowledge of the comparative anatomy of a series of organisms and some speculations as to the course of their evolution, but neither, we think, has avoided the opposite danger of superficiality. Prof. Newman's is the better book.

Our Bookshelf.

The Foundations of Colloid Chemistry: a Selection of Early Papers bearing on the Subject. Edited, on behalf of the Colloids Committee of the British Association, by Emil Hatschek. Pp. 173. (London: Ernest Benn, Ltd., 1925.) 18s. net.

MR. EMIL HATSCHKE has rendered a real service to all students of colloid chemistry by collecting early fundamental papers on the subject, six by foreign investigators being translated into English. The book makes no pretence to develop a historical account of the growth of colloid chemistry, but rather indicates certain outstanding conclusions which subsequent research has substantiated.

The first paper is by Ascherson (1840), who dealt with protein absorption at the interface: oil-aqueous solution. His results have been almost entirely overlooked by the many investigators who have since

published work on similar lines. With remarkable insight he speaks of "capillary condensation" at the interface between heterogeneous liquids, the modern notion of adsorption.

Three papers by Selmi (1845, 1847, 1850) disclose experiments and deductions little known to the majority of students. He recognised many colloidal solutions, naming them "pseudo-solutions," and anticipated the importance of the organic colloids. The pseudo-solutions could be coagulated by electrolytes, a fairly wide selection being tried out. The paper by Selmi and Sobrero, dealing with sulphur sols, is very important historically. A paper by Graham, "On the Properties of Silicic Acid and other Analogous Colloidal Substances," introduces nomenclature now firmly established.

The colloidal chemistry of metals has attracted numerous workers, and the subject lends itself admirably to quantitative treatment. It is satisfactory, therefore, to find the classic papers of Faraday (on gold sols), Muthmann (on silver sols), and Carey Lea (on silver sols). Faraday believed that his ruby sols contained solid gold in extremely fine division, and he mentions the use of a light cone to show up the particles; the Tyndall cone should really be termed the Faraday-Tyndall cone. Muthmann (1887) published his experiments on the dialysis of metal sols, an outstanding achievement in colloid chemistry. Carey Lea's work is somewhat better known, a complete edition of his papers having been translated and edited by Lüppe-Cramer. The remarkable publication of van Bemmelen (1888), "On the Nature of Colloids and their Water Content," is essential to the study of gels, and pointed to a new field in colloid chemistry.

Mr. Hatschek has provided most useful notes to all these papers, and he is to be congratulated on his work as editor and translator. The publishers have also done their work well.

WILLIAM CLAYTON.

Introductory Geology: for Use in Universities, Colleges, Schools of Science, etc., and for the General Reader.

Part 1: Physical Geology, by Prof. Louis V. Pirsson;
Part 2: Outlines of Historical Geology, by Prof. Charles Schuchert. Pp. x+693. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 20s. net.

THE text of Part 1, "Physical Geology," first appeared in 1915 in Pirsson and Schuchert's "Text-Book of Geology," a revised second edition of which was published in 1920. With the exception of the chapter on ore deposits, which has been rewritten by Prof. A. M. Bateman, Part 1 in the present volume is reprinted from the second edition of the "Text-Book." The subject is treated under two main heads, dynamical geology and structural geology. In the first section the various geological agents and their work are dealt with fully but concisely, the geological work of organic life not being neglected. The second section is a well-arranged and comprehensive account of the composition, character, relations, and structures of the rocks forming the earth's crust. In scope and treatment the whole is an excellent introduction to the subject for students, and it must also be of interest to the general reader. The illustrations are good and include both reproductions of photographs and diagrams. There is an appendix on important minerals.

Part 2, "Outlines of Historical Geology," is a greatly reduced version of the author's "Historical Geology" in the "Text-Book of Geology" of Pirsson and Schuchert. In thus cutting down the original manuscript, the author has succeeded in producing a book more suitable as an introduction to the subject. The contents are well arranged, the first chapters dealing briefly with the changing aspect of the earth's surface, evolution, fossils, and the geological record, and thus prepare the way for an account of the history of the earth during the successive geological periods. This account is related with special reference to North America, and these chapters are therefore mainly a geological history of that country. Other chapters are devoted to the coming of land life, the evolution of mammals, and man. There are abundant illustrations of fossils and restorations together with numerous palæogeographical maps. A folding geological map of North America is appended. The volume includes a very full index.

The Natural History of Wicken Fen. Edited by Prof. J. Stanley Gardiner. Part 2. Pp. 65-171. (Cambridge: Bowes and Bowes, 1925.) 6s. net.

THE second part of this valuable work on the natural history of Wicken Fen includes an account of the dragon flies, the bugs, the Ichneumonidae and some of the other less popular families of insects, the spiders, the wood lice, the leeches and the mollusca. It also contains an account of some observations on the hydrogen ion concentration of the waters of the Fen, and on its Phytoplankton, and an interesting essay by Dr. A. H. Evans on the history of Wicken and Burwell Fens.

We may congratulate the editor on the style in which his contributors have written their parts, for they write not only with authority on their several subjects, but also in a manner that interests the naturalist who has no special knowledge of the groups that are described. In the literature of the British fauna there are found many records which are simply unintelligible to any but the highly specialised systematists. There are no suggestions to excite the interest of the more general reader on the habits, associations, rarity, and other points of interest of the animals included in the long lists of specific names. There is no article in this volume to which this criticism could be fairly applied, for in every one of them we seem to catch the spirit of the true naturalist instead of that of the mere collector. With this little volume in his hand a visitor would have at least some idea as to what to look for and how to find it.

Mr. Saunderson's essay on the hydrogen ion concentration of the water is a novelty in works of this description, but we hope it will be followed by others of a similar kind. It has often been a puzzle to naturalists why some ponds are so rich in their microfauna and others so poor. Is the solution of this puzzle to be found in the pH?

Reference cannot be made in detail to the individual essays in this part of the series, but as a whole it affords additional commendation for the wisdom and public spirit of those whose efforts have led to the preservation of Wicken Fen from the destructive forces of modern civilisation. The series should be in the library of every naturalist.

Scientific Paradoxes and Problems and their Solutions ; Simultaneously Broadcast from 2LO. By A. S. E. Ackermann. Pp. viii + 131. (London: The Old Westminster Press, 1925.) 5s. net.

MR. ACKERMANN is the author of a successful book on popular fallacies, now in its third edition. Early in 1925 he was engaged by the British Broadcasting Company to give a series of talks on popular fallacies connected with engineering and science. Listeners were invited to send such paradoxes to the speaker, and the pick of the matter received by him has been collected into the volume now noticed. Some of the problems, which seem trivial to a mind versed in science, are yet a source of constant perplexity to the general public.

A great number of people are attracted by arithmetical, geometrical, and mechanical puzzles, and the author found that a surprising variety of posers, many being of a very high quality, were sent to him by interested listeners. The solutions of some of the problems included will be obvious to many schoolboys. A few of them are mere verbal conundrums. From the more elusive questions discussed we select two, which are sufficient to indicate the scope of Mr. Ackermann's book. 1. (p. 70). Given two straight bars of steel identical in every respect with the exception that one of them is magnetised, in what way can it be determined which bar is magnetised? No third article of *any kind* is to be used. You may not even balance one or both bars on a finger or finger-nail, but you may hold the bars in your hands. 2. (p. 75). In going up a wide, steep road on a bicycle or other vehicle, does it make it any easier for the bicycle rider, horse, or engine of a car if a zigzag course be taken?

The solutions throughout are given in non-technical language and should appeal to any intelligent person without specialised training in science. We foresee a wide circulation for Mr. Ackermann's book: few readers will go through its pages without finding much to instruct them—and all of it presented in an entertaining way. W. E. H. B.

Electrical Engineering. By Prof. L. A. Hazeltine. (Engineering Science Series.) Pp. xvi + 625. (New York: The Macmillan Co., 1924) 30s. net.

THE author of this volume is the professor of electrical engineering in the Stevens Institute of Technology. It is primarily intended for the students in his classes, but it will be of interest to many teachers of physics and engineering in Great Britain. The author writes clearly, his object being to explain the essential elements of electrical science and its applications. It will prove useful as a class-book, and we also think that it will be useful to the private student who has a sound knowledge of elementary physics. The rational system of units is employed, the permittivity of a vacuum being taken as $1/(4\pi)$. Some formulæ are simplified, but others are made slightly more complex. The "true" units and the "international" electric units are both given. Seeing that now testing laboratories can measure resistances, and so on, in true units with an accuracy far exceeding that required in industry, we think that the time has come when the "international" units can be regarded as obsolete. No instrument reads absolutely correctly, and the "tolerance" permissible, with a given type of instrument, is many

times greater than the possible error in calibrating the standard in true units. Mathematical proofs are always given when they can be understood by the average student, but advanced mathematical proofs are excluded. Many collections of problems are given throughout the book, and we were glad to see that the answers are given to them.

Practical Radio: including the Testing of Radio Receiving Sets. By James A. Moyer and John F. Wostrel. Pp. vii + 249. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd, 1924.) 8s. 9d. net.

RADIO broadcasting has greatly interested the public in radio science. There are many amateurs who have an excellent working knowledge of the art but lack that specialised knowledge of the science which alone can give them the confidence necessary for success. This book is clearly written and can be recommended to any one who wants to know standard modern practice and desires a simple introduction to elementary theory. A chapter is devoted to the future of radio, but the author rather confines himself to the history of past triumphs. A good description is given of the apparatus used for transmitting photographs over long telephone wires on a commercial scale; vacuum tube amplifiers, photo-electric cells and synchronising arrangements form an essential part of the method. It is therefore an adaptation of devices developed in connexion with radio communication, telegraphy and telephony. Future improvements in radio reception will probably consist of replacing storage batteries and dry cells by devices which can be connected with the electric supply; for example, a suitable thermocouple. As amplifiers become more sensitive a large antenna becomes unnecessary. Many sets operate with a loop at present, but in the future this loop will probably be very small. The elimination of static disturbances by directive reception is also mentioned.

Faune de France. 9: Amphipodes. Par Ed. Chevreux et Louis Fage. (Fédération Française des Sociétés de Sciences Naturelles: Office Central de Faunistique.) Pp 488. (Paris: Paul Lechevalier, 1925) 60 francs.

THE volume opens with a short statement of the characters of the order Amphipoda and of its three suborders, followed by an account of the habitats in which Amphipoda occur, the methods by which specimens may be obtained, studied, and preserved, and by a useful description of the external morphology and internal structure. Tabular keys are provided to the families, genera, and species—some 320 of the latter being considered. Under each species is given a concise statement of its characters—illustrated by clear line drawings, for the most part original—and of the distribution of the species in France, with a note of the neighbouring countries from which it has been recorded. Appended is a list of works on Amphipoda and there is an adequate index.

The present volume, like its predecessors in the same series, will receive a warm welcome in Great Britain, and will be of great service to those interested in the order of which it treats.

Carnot's Cycle and Efficiency of Heat Engines.

ON p 326 of NATURE for August 29 appears an abstract of a paper by Dr J S Haldane, which he read before the Institution of Mining Engineers on June 16. In this paper he has "thrown to the winds" the usual academic teaching in regard to the efficiency of a Carnot cycle, and has put forward a claim that another cycle has a greater efficiency. This, which for brevity we will call the Haldane cycle, consists of an adiabatic expansion BC (Fig 1) followed by an isothermal compression CA and a constant volume heating AB. In the discussion on the paper, I proved that this cycle has only about half the efficiency of a Carnot cycle working between the same limits of temperature. This proof did not make use of Carnot's principle, but required only a knowledge of the thermal properties of air, which was treated as a perfect gas. In such a case it is perfectly easy to calculate the work done and the heat changes and therefore the efficiency.

Dr Haldane has challenged these conclusions, their truth, however, can be seen in other ways.

In the Haldane cycle heat (say H_1) is taken in along AB and heat H_2 is given out in the condensation along CA (see Fig 1). The balance of work done is the difference between the work of expansion along BC and the work of compression along CA, this balance is represented by the area ABC.

Now to increase the efficiency we require to increase the work for a given quantity of heat rejected along CA. This can be done by replacing AB by an adiabatic compression AD which raises the temperature to that at B followed by an isothermal expansion DB. By making this change we have obviously practically doubled the area representing the balance of work available without altering the amount of heat H_2 rejected. But the new cycle so obtained is a Carnot cycle; this has therefore a greater efficiency than a Haldane cycle. When the difference of temperature is small the double area implies double efficiency, because H_1 and H_2 are nearly equal. But detailed calculation shows that it is practically so for differences as large as 200 degrees.

Of course more heat is now taken from the boiler (along DB), because the principle of conservation of energy must be satisfied—unless this principle is another which may be "thrown to the winds".

These conclusions can be verified by detailed calculation for the case where the working substance is a perfect gas. Air at moderate pressure is so nearly a perfect gas that they cannot be far wrong for air. What Carnot did was to give reasons for declaring that the efficiency for a given range of temperatures must be independent of the substance used in the cylinder in the case of reversible cycles. Whatever the efficiency may be for a perfect gas must be precisely the value for air also or for steam or even for ice. His reasoning was imperfect because it was based upon the caloric theory of heat. But it

had such a form that when the energy nature of heat came to be recognised, the reasoning was easily transformed by Clausius (1850) and Kelvin (1851) so as to suit the general law of conservation of energy. The reasoning was transformed although the conclusion remained the same and is still known under Carnot's name.

The proof of the law of efficiency does not rest on the performance of actual steam-engines. These are always less perfect because they are not reversible. To those who cannot rise to the necessary heights of abstract reasoning the Carnot-Clausius-Kelvin proofs can be replaced by the more tangible facts that the thermal properties of any substance are connected together by relations which require the exact truth of the Carnot law. For example, the latent heat of a substance can be calculated from observations of pressures, volumes, and temperatures. The latent heats of substances would not be what they are if the law were untrue. It will take more than the unsupported assertions of Dr. Haldane to disturb convictions based upon the immense amount of evidence in the realm of physics which requires the truth of Carnot's theorems.

Mutant Groups in Nature.

WHILE staying at Val d'Isère (Savoie) this summer, I noticed some facts which seem worthy of record as bearing on the evolutionary importance of mutations. *Gentiana campestris* L. was an abundant plant in many localities round the village. Not infrequently variants were noted in which the corolla was white and the leaves paler green than normal ("albinos"). It is not to be doubted that such forms have arisen from the type by a recessive mutation. Sometimes these mutants were found singly. This is in my experience the usual state of affairs with white-flowered mutants of other wild species (e.g. wild hyacinth), and was also the case with pink-tinged *Saxifraga oppositifolia* noted by me in Spitsbergen in 1921.

The fact which struck me as interesting, however, was the discovery, on five occasions, in quite separate localities, of groups of albinos. In two cases the groups were small, comprising only a score or so of individuals. In two further cases the number of individuals in the group was several hundreds, and in the last and most remarkable group it was certainly well over a thousand, and very possibly several thousands. This largest group was found on the left bank of the Charvet torrent, almost exactly at the waterfall which forms a conspicuous object in the view from Val d'Isère, about 2 miles up the Calabourdane valley. It would be interesting if botanists who were in this area would visit it from time to time to see whether it maintained itself. Over an area of ground about 70 paces long and 15 to 20 paces broad, albinos were very abundant, only one or two scattered type plants (purple-flowered) were discovered, after some searching. Round this patch was a zone apparently unsuited to the growth of this plant, extending away from the stream for 40 or 50 yards, upstream for nearly as much, and downstream for almost 100 yards, the stream itself formed a barrier on the fourth side.

The other two large groups, one of which was about 10 x 15 yards in extent, also showed a very few normal plants. In one at least of the small groups, no normals were found within this albino group. The isolation of the group by a zone unsuited to the species was clear also in one of the moderate groups, but definitely did not exist in one of the small ones. I have no notes on the point for the remaining two groups.

These groups, all belonging to a distinct and obviously mutant type, strongly recall the findings of R. E. Lloyd in rats in India ("The Growth of Groups in the Animal Kingdom," London, 1912). Here, however, the fate of the group might be followed year by year, which was difficult or impossible for the rats.

The most probable explanation of the existence of such groups is that they are all descended from a few or probably a single mutant ancestor. The ecological isolation of the areas occupied by some of the groups is interesting. When such isolated areas occur, then, should especially adverse circumstances kill off a species over part of its range, if a mutant chance to be the first to recolonise an isolated patch, it has a good chance of populating the whole patch; whereas (if recessive and non-advantageous) if not isolated it will tend to be swamped. Once the patch is colonised with the mutant, it will not be easily invaded by the type unless the mutant is markedly less hardy. For a detailed discussion of these points, see C. S. Elton, 1924 ("Periodic Fluctuations in the Number of Animals," etc., *Brit Jour Exp Biol*, 2, p. 119), and A. L. and A. C. Hagedoorn, 1921 ("The Relative Value of the Processes causing Evolution": The Hague). It is to be noted that the patches tenanted by the white plants were not newly exposed ground, but similar in every way, so far as could be seen, to the neighbouring areas where the type plant was abundant.

It is in any case interesting to find a mutation which by analogy is almost certainly recessive, and most probably less vigorous than the type, capable of colonising and holding in force areas as large as that described. It shows how easily mutations may become established in nature. If the mutation were of smaller extent and less unfavourable it would have still more chance of surviving, though less of detection; if it possessed a biological advantage over the type, *a fortiori* it would survive still more readily. In any case, the importance of tiny semi-isolated areas within the habitat of a species may be expected to provide, as in this case, occasional "reservoirs" of mutants. Such "reservoirs" would also be expected in normally self-fertilised species, though the isolation here would be physiological.

I have no doubt that similar cases must be known to botanists, and that many more are awaiting discovery. Meanwhile, I venture to record these observations for what they are worth.

Coastal Refraction of Wireless Waves.

DR SMITH ROSE, in his letter on this subject in NATURE of September 19, has directed attention to the striking discrepancy between theory and experience in the matter of coastal refraction of wireless waves. It may be of interest to point out that the conclusion, to which he is led from Zenneck's analysis, that waves travel with a greater effective velocity the lower the conductivity of the surface, though contrary, I believe, to what is now generally accepted, is supported by quite simple reasoning.

If we make Zenneck's assumption that at a considerable distance from the transmitter we have to deal with a single wave, sensibly plane, it follows that (neglecting the conductivity of the air and assuming its S.I.C. is unity) the wave must be travelling with the speed of light.

Further, since there is only one wave, the conditions at the surface must be those for an incident and refracted ray but without reflected ray,¹ that is, the wave must be incident at the critical, or Brewsterian, angle of incidence (i) given by

$$i = \tan^{-1} \mu \quad (1)$$

where $\mu = \sqrt{K - \frac{2j\sigma}{n}}$ is the refractive index of the ground and

K is the S.I.C. of the ground,
 σ is the conductivity (E.S.U.) of the ground,
 n is the frequency of the waves.

The forward tilt of the waves ($90^\circ - i$) implied by equation (1) is identical with that obtained by Zenneck.

The velocity (V) of such a wave along the surface can only be defined as the product of frequency into wave-length (i.e. distance apart of two crests) measured along the surface, so that we see from Fig 1

$$V = n \frac{\lambda}{\sin i} = c / \sin i = c \sqrt{\frac{\mu^2 + 1}{\mu^2}} \quad (2)$$

(where c = velocity of light), and this is identical with the expression for superficial velocity obtained by

FIG 1.

FIG 2.

Zenneck and referred to by Dr. Smith Rose. Now μ decreases with decreasing conductivity, so the velocity will increase and be greater over land than sea.

If V_1 is the velocity over sea,
 V_2 " " " " land

The ratio V_1/V_2 , which may be called the coastal refractive index (μ_c), is obtained by

$$\mu_c = V_1/V_2 = \frac{\sin i_2}{\sin i_1} = \sqrt{\frac{\mu_2^2(\mu_1^2 + 1)}{\mu_1^2(\mu_2^2 + 1)}} \quad (3)$$

(where μ_1, μ_2 are the refractive indices for land and sea). But, in the case of sea, $\mu_1^2 \gg 1$ for commercial frequencies, so that

$$\mu_c = \sqrt{\frac{\mu_2^2}{\mu_2^2 + 1}} \quad (4)$$

The coastal refractive index is thus less than one.

In the face of the experimental evidence,² which seems to me very decisive, we are left with the conclusion that coastal refraction must be the result of other causes than a difference in superficial velocity.

I think that there is a possible explanation in the fact that there is greater absorption of the waves on land than on sea. The part of the wave-front on land must, for this reason, be weaker than that on sea, with the result that a continual transference of energy must take place across the boundary at right angles to the general direction of travel of the waves. This will give rise to a kink in the wave-front in the

¹ I now find Bouthillon has used much the same argument in a criticism of Zenneck's work (see *Onde Electrique*, May 1923), but not in connexion with this particular problem.

neighbourhood of the boundary in some sort of manner as shown in Fig. 2.

This would account qualitatively for the facts. A mathematical development on these lines would be necessary in order to show whether it also gave quantitative agreement

Spermatogenesis of Spiders.

I HAVE been much interested in Prof. Ernest Warren's letter in NATURE of September 12 on the spermatogenesis of spiders, in which he claims amitotic division of spermatogonia, an abnormal type of maturation, and finally the formation of many spermatozoa from chromatin bodies, bereft of cytoplasm.

I recognise that it is naturally difficult for any one, in the limited space afforded by a letter to NATURE, to give an adequate account of the phenomena described by Prof. Warren; nevertheless, I feel that there is need for caution in accepting his results. The spermatogonial nucleus is polymorphic and lobulated, in itself no evidence of amitosis: the great Meves himself mistook the polymorphism of amphibian germ cells for amitosis—a mistake finally cleared up by Champy.

The formation of more than four spermatids from one spermatocyte is known in moths, where this effect is brought about by an extra, but normal, mitotic division.

Prof. Warren's figures 9-12 seem to recall apyrene sperm formation, or the degenerative changes found in many effete insect germ cells.

I feel that while Prof. Warren has described what may be an interesting cytologic phenomenon, he has not convinced your readers that fertilisation in his spider is not brought about by a normally formed sperm.

Nevertheless, I would be glad to see some of Prof. Ernest Warren's material upon which his results are based

J. BRONTÉ GATENBY.

Trinity College, Dublin,
September 14.

PROF. WARREN'S most interesting letter in NATURE of September 12 on the subject of spiders concludes with the challenging remark that "It would be obviously absurd to suppose that the mechanism of heredity differs fundamentally in certain spiders from that in other organisms." Why absurd? Spiders belong to a line of evolution remote from the mammals, for example, and a line which obviously "stuck"; and may this not be because its mechanism of heredity was not entirely satisfactory? Other lines carried on to the higher groups, and may it not be just because mammals possess a somewhat different and more useful mechanism for their heredity?

Antimonial Analogues of the Cacodyl Series.

IN view of the interest now manifested in organic derivatives of antimony, we desire to place on record our discovery of the antimonial analogues of the cacodyl series on which we have been engaged during the last three years.

Although aromatic antimonials are known containing the metal combined with one or two aryl groups,

so far the only well-authenticated aliphatic antimonials belong exclusively to the tertiary stibine series in which antimony is associated with three alkyl radicals as in trimethylstibine, $(\text{CH}_3)_3\text{Sb}$.

The following thermal decomposition,

has been generalised for the dihalides of trimethylstibine and leads to dimethylstibine chloride, bromide and iodide corresponding with cacodyl chloride, bromide and iodide in the arsenical series.

Dimethylstibine oxide has also been obtained, and the antimonial series has been completed in this laboratory by Mr. V. E. Yarsley's collaboration in the preparation of dimethylstibine cyanide, the analogue of Bunsen's cacodyl cyanide.

Antimony cacodyl itself has not been isolated in a state of purity, although its existence among the reduction products of dimethylstibine bromide has been demonstrated.

By carrying demethylation a stage further,

we have obtained another new series of alkyl antimonials in which the metal is associated with only one methyl radical.

The following historical coincidence may also be of interest. Cacodyl and cacodyl oxide were originally prepared by L. C. Cadet de Gassicourt in 1760 when engaged on service work for the French army of that day, whereas the investigations referred to in this note have arisen out of war work for the British Military Authorities.

Thunderstorms and the Sound of Lightning.

I WAS interested in reading the recent correspondence in NATURE about the sound of lightning, for I also have once heard it. It was in East Griqualand one evening when, in the midst of a storm, I saw a blinding flash, followed almost instantaneously by an explosion like a shell. But between the flash and the crash there was a distinct small pistol-shot-like sound, immediately after the flash.

The Transvaal is a noted place for thunderstorms. On Christmas Day 1923 I witnessed what I should imagine must almost be a world record in the way of storms. It occurred in the late afternoon and evening over the Pretoria district. From my balcony I had a fine view of it about twenty miles away on the horizon. There were really two storms, one about 6 and the other between 7 and 8.30. I saw the latter. The flashes for about twenty or thirty minutes during the time I looked on must have been at the average rate of well over one per second. Mr. Stewart, the Government meteorologist at Pretoria, kindly gave me some statistics of the storm. He said that in three minutes there were the astonishing number of 360 flashes, an average of two per second. I should imagine that for something like an hour perhaps there were an average of 100 flashes per minute. It was a wonderful sight: the sky in the north towards Pretoria was simply one blaze of light. The damage done by the hail was tremendous, and one woman died from shock. It would be interesting to hear if any of the widely spread readers of NATURE in other parts of the world have ever seen a worse thunderstorm.

The Mineral Elements in Animal Nutrition.¹

By Dr. J. B. ORR.

SINCE the time of Lavoisier, research in nutrition has been directed chiefly to the chemistry and metabolism of organic compounds, *i.e.* proteins, fats, carbohydrates and allied substances, and in tables of rations the food requirements of animals have been expressed in terms of these or their equivalents. During the past half-century, however, an increasing number of workers have become interested in the rôle played by inorganic salts in nutrition. The information being yielded by the researches of these workers is throwing new light on many fundamental problems of biology, and some of it appears to be of potential economic value in animal husbandry.

From 10 to 25 per cent. of living matter consists of organic compounds of which the colloidal material of the protoplasm is formed. The remaining 75 to 90 per cent. consists of water and inorganic salts. In the recent literature of animal husbandry, the elements of these salts have been somewhat loosely termed "the mineral elements," to distinguish them from the carbon, hydrogen, oxygen and nitrogen of the organic compounds. In living matter these mineral elements are present, partly in chemical combination with, and forming an integral part of, organic compounds, and partly free or potentially free, either in solution as salts or ions in the water of the protoplasm, or in a temporary loose union with the colloids.

The fundamental nature of the functions of the so-called mineral or inorganic salts in life processes is at once apparent when we consider the part played by them in the origin of the cycle of energy exchanges which occur in the "organic world." All forms of life depend ultimately upon the transformation of the energy of sunlight into chemical energy. The power of carrying out this fundamental process, which can be regarded as the real origin of life, is possessed by inorganic salts in colloidal solution. Photosynthesis with the production of formaldehyde, which contains the trapped energy of the sunlight, arises from the action of sunlight and inorganic salts on water and carbon dioxide. According to Moore, chlorophyll itself is a product of photosynthesis, and its chief function is probably not the primary one of deoxidising the carbon dioxide and thus charging the carbon with energy, but of changing the formaldehyde into higher carbon compounds. Hence the beginning of life-processes lies in the action of radiant energy on inorganic salts. The carbon atom is harnessed as the most suitable vehicle for conveying the chemical energy formed. The giant molecules and colloidal aggregates with their complex carbon-containing compounds, which have been regarded as the fundamental organic substances, are really secondary developments to secure that degree of stability and complexity required for the evolution of higher forms of life. Thus the true basis of protoplasm is the saline solution which forms from 75 to 90 per cent. of its bulk and still resembles the sea water from which it originated.

It is impossible here to do more than refer briefly to the nature of the functions of the inorganic salts

and ions. As has been already indicated, these functions are intimately connected with colloidal activities. The visible phenomena of life are the resultants of an enormous number of chemical and physical changes in the colloids of protoplasm and of exchanges between masses of protoplasm separated by membranes or interfaces. But these changes in the physical state of colloids are determined by the association and dissociation of colloids and inorganic ions. These ions also affect the permeability of membranes and the tensions at interfaces. Hence, in a real sense, protoplasmic activity is regulated by the action of the mineral elements in solution in the protoplasm or attached to its colloids. Thus, in the contraction of muscle, though the ultimate source of energy is the oxidation of organic compounds, the initiation of the process, the mechanism by which it is carried through and the factors by which it is controlled, depend on the action of the ions and salts present, which involve changes in osmotic pressure and other physical forces.

The foregoing considerations suggest that definite degrees of concentration of the various inorganic ions in the cell fluids are necessary for the maintenance of normal protoplasmic activity. This has been fully demonstrated by work done to determine the effect of changes in the normal concentration of the different ions. The results of experiments with unicellular organisms and with isolated organs such as the perfused heart have shown that slight alterations either in the absolute or relative concentrations of any of the inorganic ions may accelerate, retard, or even reverse processes being carried out by means of the colloidal mechanism.

In the animal body these changes in the concentration of the inorganic ions can be correlated with changes in the functions of the organs. Thus, all the organs regulated by the central nervous system depend for the integrity of their functions upon the maintenance of definite ratios of calcium, potassium, and sodium in the fluids within the nerve tissues. Changes in the relative proportions of these are accompanied by alteration in the excitability of nerve and in the irritability of muscle. The classical experiments of Ringer on the perfused heart show that minute changes in the concentrations of calcium or potassium in the perfusing fluids have a profound effect on the activity of the heart. These examples are merely illustrations of the general law that any disturbance of the normal physiological balance of the salt solution of the body is accompanied by a correlated impairment of function.

The body is remarkably efficient in maintaining this balance, in spite of the fact that there is a continuous loss in the excreta, and the mineral matter of the food is liable to be very different in composition from that found in the blood. Within limits, the elements present in excess tend to be excreted and those deficient to be conserved. The bones act as a reservoir, especially for calcium and phosphorus, the two required in largest amounts. Reserves can be deposited in the bones when the supply is ample, and mobilised in

¹ From the presidential address delivered at Southampton on August 31 before Section M (Agriculture) of the British Association.

times of need. It is probable that this function of the bones, namely, regulating the supply of mineral elements to the body fluids, is as important as the more obvious one of providing a rigid framework. It is probably more fundamental, for, when the available mineral matter is insufficient to maintain both the physiological balance in the blood and the rigidity of the skeleton, it is rigidity which is sacrificed. There is little doubt that in most diseases affecting the bones the skeletal symptoms are only secondary manifestations of the influence of some factor, often a dietary one, which upsets the balance of mineral elements in the blood.

Under experimental conditions it is possible by feeding diets with marked deficiencies or excesses of some of the mineral elements to produce conditions of malnutrition which are so definite and marked that they are as easily recognised as definite diseases; indeed similar conditions occurring in practice are regarded as definite diseases. Thus, primary anaemia, simple goitre and rickets are produced by deficiency of iron, iodine and either calcium or phosphorus respectively. An interesting case of a disease due to an excess of a mineral element is reported by McCollum, who regards an inflammatory condition of the eyes, resembling xerophthalmia, which he calls "salt ophthalmia," as due to excess of chlorine in the food.

In addition to these diseases due to excesses or deficiencies of mineral elements in the diet, in which the symptoms form a definite and easily recognised picture, and the cause is admitted, there are conditions of malnutrition due to the lack of balance of the mineral elements in the diet, where the signs are much less obvious. In young animals there may be retarded growth without any definite pathological symptoms. The only reason for supposing that such animals are not in a perfect state of health is that their rate of growth is not optimal, as is shown by the fact that improvement follows the adjustment of the mineral balance in the food. Thus, Kellner obtained an increased rate of growth in calves by the addition of a calcium salt to a diet on which the animals grew at an average rate and showed no signs of obvious ill-health. In some work, not yet reported, we have found that the addition of traces of iodine to the diet of stall-fed calves in winter increased the rate of growth as compared with that of control animals whose condition would be regarded as normal. Further, it has been shown recently that the supply of minerals in the food of the mother may have a profound influence on the vitality of the young at birth and for some time after, even where there may be no obvious effect on the mother. Thus Hart, Steenbock and Humphrey have noted that deficiency of calcium in the diet of cows may lead to the birth of dead or weakly calves, and Ennis Smith has shown that deficiency of iodine in the food of pigs may lead to the birth of dead young, although there is not, in either case, any obvious pathological condition apparent in the mothers.

Some attention has recently been devoted to the question of an increased susceptibility to certain infectious diseases in cases of malnutrition due to deficiencies of minerals. We have noted in feeding experiments that the mortality from intercurrent infec-

tions is much higher in the groups fed on diets which, for experimental reasons, are ill-balanced or deficient in mineral matter. Meigs has noted a similar increased incidence of diseases in cows on diets deficient in calcium.

It may be of interest to consider some reasons which can be adduced for believing that the danger of deficiencies of minerals in the food of farm animals has been increasing in recent years. During the past half-century, the types of animals after which breeders have been striving are those whose young have a very rapid rate of growth, or whose females have a great capacity for producing the constructive materials required for growth. A remarkable degree of success has attended these efforts of the breeders. Some breeds of pigs will increase in weight from 2 lb. to 2 cwt. in six months. There are dairy cows which can secrete in their milk as much as 10-12 lb. of solid matter per day. There are hens that lay 200 to 300 eggs in a year. Now, the faster the rate of growth, the greater must be both the absolute amount of mineral matter required in a given time and the proportion of mineral matter per unit of energy in the food. The following table shows that the percentage of mineral matter in the milk of different species, and also the amounts relative to the energy values, are in proportion to the rates of growth.

TABLE I.

	Number of Days in which Weight of New-born Animal is doubled	Milk of Species contains	
		Ash per cent.	Ash per 1000 Calories.
Man . .	Days. 280	0.25	Grams. 3.7
Cow . .	47	0.72	10.5
Pig . .	14	1.03	10.9
Rabbit .	6	2.50	15

Hence, in modern types of animals the mineral requirements have increased *pari passu* with increased capacity for growth, and the danger of malnutrition through an absolute deficiency of any of the mineral elements, or a lack of balance of these constituents of the food, is correspondingly increased. As a matter of fact, it is found that malnutrition due to disordered mineral metabolism occurs most readily in those animals that are growing fastest. In experiments with both dogs and pigs it has been found that symptoms of rickets tend to appear earliest in those that are growing most rapidly.

Concurrently with the evolution of these faster growing types, with their greater need for each of the essential mineral elements in their food, and for a more perfect balance of these elements, there has been an increasing use of concentrates to support rapid growth. These concentrates, which consist chiefly of commercial by-products of cereal grains and tropical seeds and nuts, are markedly deficient in some of those mineral elements which are required for growth, or for the production of growth material. The following table compares the mineral matter of some of these artificial feeding stuffs with that of milk and good mixed pasture, the only two foodstuffs of which the

mineral content corresponds approximately with the requirements of herbivora.

It is seen from the table that foodstuffs such as tubers and cereals are deficient especially in calcium, chlorine and sodium. Most concentrates resemble cereals in their mineral composition.

A third factor with an adverse effect on mineral metabolism is the increasing tendency to feed large numbers of animals together. This necessitates for practical purposes the adoption of fixed standard rations, which may be fed with little or no change for months on end, or even through the whole life-cycle of the animal. Unless such rations are almost perfectly constituted with regard to their mineral content, there must be a cumulative effect of any deficiency or lack of balance which would not occur in the case of either single animals or small groups, fed in a more haphazard fashion. As a matter of fact, in practice, the cottager's pig, with a varying diet consisting largely of scraps, differing in kind from day to day, seems less liable to disease and more successful in bearing and rearing large litters than pigs fed in large numbers under what might almost be termed factory conditions.

The reasons adduced above seem valid enough to justify the fear that, under modern conditions of intensive production in animal husbandry, there is a danger of malnutrition and disease arising on account of defects in the inorganic portion of the ration. Acting on this belief, attempts have recently been made to increase the rate of growth and improve the condition of animals by the addition of various mineral salts thought to be present in their rations in insufficient amounts. In many cases marked beneficial effects have been noted. Thus in pig-feeding, the cereal grains and most other foodstuffs commonly used in making up rations are deficient in calcium, sodium, chlorine and, in some cases, iron and iodine, and it has been found that growth, health and reproductive capacity all tend to be improved by the addition to the food of salt mixtures or foodstuffs such as fish meal or meat meal which are rich in these elements.

In poultry it has been found, in experiments carried out at Ohio and at stations in Scotland and Northern Ireland, that even though the birds have access to green food and lime or oyster-shell, egg-production can be increased by the addition to the cereal rations usually fed to poultry of a mixture of those salts which are present in the ration in smaller proportions than in egg.

Of all farm animals, the stall-fed heavy-milking cow

is the one most likely to suffer from depletion of minerals from the tissues and consequent malnutrition, on account of the fact that it loses from its body such relatively large quantities of mineral matter in the milk. In short tests, running for a few days or weeks, the adjustment of the mineral matter of the ration is not usually followed by increased milk production, because the cow will continue to give milk even though the body is being depleted of minerals. But the influence of adjusting the ration is seen towards the end of a long lactation or in a subsequent lactation. In recent tests at Beltsville and Ohio and at Aberdeen, which have been carried over one or more complete lactation periods, it has been found that the adjustment of the ration by the addition of salts present in too small amounts has resulted in a rather greater yield of milk and in an increase in breeding capacity and decrease in disease.

Some interesting cases of deficiencies of one or more minerals in natural pastures have been discovered. In an investigation being carried on partly at the Rowett Institute and partly at the Nutrition Institute at Cambridge, it has been found that there are marked differences in the mineral content of uncultivated pastures grown in different localities, and that there appears to be a correlation between the mineral content of the pasture and its feeding value, as determined by the number of stock it can carry, and the health and breeding capacity of the stock. An interesting fact brought out is that, where the sheep have a choice of pastures, they actually eat the herbage the mineral composition of which most closely approximates to that of good cultivated pasture. As we saw above, good pasture contains the various elements in proportions somewhat similar to those which are found in milk, and might therefore be presumed to be suitable for growth and the maintenance of health, as indeed is found to be the case in practice.

In various countries where the modern type of rapidly growing animal has been put to graze on uncultivated pastures, malnutrition, as shown by stunted growth, low milk yield, or increased liability to disease, has appeared. Thus, in South Africa, Sir Arnold Theiler and his associates have shown that deficiency of phosphorus in the pastures is the cause of pica (depraved appetite), which is prevalent in cattle in certain districts there and leads to the ingestion of the organism which causes lamziekte, and that the condition can be prevented by feeding bone-meal, or any foodstuff rich in phosphorus. Not only does this adjustment of the mineral intake prevent the disease, but the general condition of the animals is also improved.

The two elements most frequently deficient in pasture are probably calcium and phosphorus. Malnutrition due to deficiency of these has been noted in various districts in Australia, New Zealand and India, and in the Falkland Islands. Other minerals may, however, also be deficient. Thus, in the North Island, New Zealand, Aston has found that deficiency of iron is the cause of malnutrition in animals which are grazed continuously on certain areas. The condition is avoided if the animals are transferred for a time to an area where the pasture is richer in iron. The symptoms of the disease can be relieved by feeding iron salts. It is probable that a similar condition

occurs in parts of the Cheviots where soil conditions are similar and the sheep show symptoms which resemble those described by Aston.

These examples of malnutrition in stock, associated with deficiency of one or more mineral elements in the food, are sufficient to show that the dietary conditions which produce such forms of malnutrition are fairly widespread. They also show that there is a possibility of remedying the defects if the nature of the deficiencies be known.

In order to be able to make the necessary adjustments, it is necessary to know the amounts of each of the minerals which should be present in the ration to meet the requirements of the animal. But this depends on the extent to which they are absorbed from the alimentary canal. There might be an abundance in the food, but owing to factors which affect absorption adversely, only a small proportion of what is present in the food may pass through the wall of the intestine into the metabolic field. For example, in the case of calcium, which is probably the element which involves most difficulty in this respect, the amount absorbed, as calculated from the intake in the food minus the output in the faeces, may vary from nil to over 80 per cent. of the amount ingested.

Excess or deficiency of one mineral element may interfere not only with the absorption but also with the utilisation of another. Thus, for example, excess of magnesium interferes with the assimilation of calcium, the ratio of sodium to potassium affects the assimilation of both calcium and phosphorus, either too much or too little oil in the diet decreases the amount of calcium absorbed from the intestine. So the ratios of the different minerals to each other and to the organic constituents of the food are almost as important as their absolute amounts.

Recent work on the ultra-violet irradiation of animals is of great importance in this connexion. The beneficial effects of sunlight have been recognised for many generations. Within the past few years it has been shown that the beneficial effect of sunlight in nutritional diseases such as rickets can be obtained from artificially produced ultra-violet rays.

At the Rowett Institute we have found that when animals are subjected to the influence of these rays the amounts of calcium and phosphorus absorbed from the intestine tend to be increased, or at least the amount excreted in the faeces is decreased, even though at the same time the amount excreted in the urine may be increased. This result, which has an important bearing on mineral metabolism, has also been obtained by other workers. It is of interest to note that the influence of irradiation on the absorption of minerals from the intestine appears to be greatest when the diet is badly balanced.

Ultra-violet irradiation is probably of very great practical importance in milk production. It has been shown by balance experiments that there is difficulty in preventing a loss of calcium from the body of the cow at the height of lactation, when the cow is fed indoors, and there is reason to believe that this loss of calcium is a predisposing cause of some of the diseases prevalent among high-milking cows. It has been found that irradiation at the height of lactation

can decrease the loss of calcium in goats, or even convert a negative balance into a positive. The practical value of irradiation will, however, not be demonstrated until experiments have been carried out with large groups of stall-fed cows in winter, to determine whether the irradiation will favourably affect milk yield, breeding capacity and health.

From what has been said regarding factors which affect the assimilation of minerals, it will be readily understood that, before the mineral content of a ration can be adjusted, it is necessary to consider all the existing dietary factors. Even when all this has been done, it is impossible, in the present state of our knowledge, to do more than make an empirical adjustment by adding inorganic salts containing elements thought to be deficient in the ration. In a few cases we can predict, with some degree of certainty, that beneficial results will follow such adjustments, but in most cases the attempt must be regarded as an experiment, the results of which may or may not justify the continued use of the salt mixture tried.

It is obvious that the use of a stereotyped salt mixture with different rations, and for animals of different ages, and even of different species, is not warranted. In feeding experiments errors arise from the assumption that the addition of such mixtures obviates any necessity for further consideration of the mineral requirements of the animal, or of the influence which may be exercised by inorganic salts present in foodstuffs, the value of which is being tested. Under practical conditions, the use of such fixed mineral mixtures proves beneficial in many cases because they are rich in those inorganic constituents which are most frequently deficient in concentrates, but in cases where the ration is already rich in some of the minerals present in the mixture, the resulting excess may be harmful. No mineral mixture is a panacea.

Our knowledge of this subject is, therefore, still so scanty that it forms a very uncertain guide to the stock-farmer. It is sufficient, however, to warrant his testing, under practical conditions, some of the results which have been obtained under experimental conditions. The results of such tests, if positive, would secure the early application in practice of information which we already possess, and, whether positive or negative, would be a valuable guide to further efforts to increase that part of our knowledge which is of immediate practical value.

Though this practical experimental work is important because it may yield results of immediate economic value, yet with regard to the future it is not more important than academic research. Valuable results are likely to be yielded by further investigations being carried out on the interactions of colloids and inorganic ions, on the influence of the electrical charge and chemical characteristics of the ion on these reactions, on the effects of radiant energy on the processes associated with mineral metabolism, and on the relationship of these to both normal and pathological processes in the body. In this region, which we have only begun to explore, there seems to lie the key to the solution of many obscure problems, both of the normal metabolism of health and the abnormal metabolism of disease.

The Discipline of Chemistry.¹

By Prof. CECIL H. DESCH, F.R.S.

TWO tendencies are clearly visible in the chemistry of to-day, and are profoundly affecting our methods of study and instruction, and also the direction of research. On one hand, chemistry, like every other science, is being split up into a number of distinct specialisms, and workers are tempted or even compelled to confine themselves to a narrow field; on the other, the boundaries between the several sciences are becoming less definite, through the development of border sciences, which themselves become new specialisms. In so far as it is possible to arrange the abstract sciences, in a linear series, chemistry may be said to depend upon physics, as the biological sciences in their turn depend upon chemistry, the theoretical part of each being built up on the established laws of the preceding science as a basis. Physics has gone far to provide the required basis for chemistry, and each new advance in physics suggests new ideas in chemistry. Chemistry in its turn is providing a basis for biology, although more slowly than had been hoped. Great as have been the triumphs of organic synthesis and of investigations of the colloidal state, the chemical study of living organisms is still looking to chemistry for more help than it has yet received.

Whether we look at the serious publications dealing expressly with the progress of science or at the mass of popular articles in newspapers and periodicals, we see that the centre of interest at the present day lies in the new discoveries and hypotheses of physics. There is no question but that the structure of the atom, the theories of relativity and of quanta, the existence of the ether, and the results of the examination of crystals by means of X-rays, interest the educated public more deeply than any questions in chemical or, probably, in biological science. On the other hand, there is little public curiosity in regard to the advance of chemical science. A few of its applications, and those mainly concerned with warfare, attract attention from time to time, although the progress of agricultural chemistry, the most important of all from a national point of view, is shamefully neglected, in spite of the admirable work which is being done at Rothamsted and elsewhere. The public interest in chemistry does not extend far beyond poison gases and dyes. The progress of pure chemistry and the development of chemical theory are followed only by a small body of specialists, engaged in teaching or research, and of students whom our present system of scholarships and degrees forces more and more to become specialists, even at a very early stage of their studies. Perhaps this state of things is responsible for a certain attitude concerning the future of chemistry which may be traced, in implication rather than expression, in the work of some chemists at the present day. It appears to be thought that chemistry is fated to become a branch of physics, and thus to lose its own peculiar discipline, leaving its long-established methods to chemists engaged in operations of a routine character, whilst new knowledge is being acquired by the application of physical

methods of experiment, and interpreted by the methods of mathematical physics.

The knowledge of the internal structure of the atom, and consequently of the manner in which atoms may unite chemically with one another, has advanced with such extraordinary rapidity that it has seemed that chemical facts must henceforth be regarded in an entirely new light. If we accept the view that protons and electrons are the units of which all atoms are composed, the forces between them being purely electrical, and that the whole system of the chemical elements may be built up in a perfectly regular and systematic fashion from these units, whilst the structure of each atom enables us to predict how it will enter into combination with other atoms, then it would seem that chemistry should in course of time become a purely deductive science. If such a state of things were to come about, experiment in chemistry would be unnecessary, since all facts could be deduced from certain general principles and from fundamental physical constants which would by then have been determined with great accuracy. Chemists, however, know that this is not how their science has advanced or is likely to advance. Chemistry is an experimental science, which progresses by the application of a definite discipline, obtaining conclusions by induction from the observed facts, and making use of deduction from a small number of well-tried hypotheses where required.

Granting the theoretical possibility that atomic theory might become so perfect that the facts of the chemical structure of molecules might be deduced from a comparatively limited mass of data, it would nevertheless remain true that the labour of such deduction would be beyond human powers, except in relatively simple cases. We can scarcely imagine the properties and synthesis of indigo being deduced from the internal structure of the atoms of carbon, nitrogen, oxygen, and hydrogen, although it is possibly true that the one is implicit in the other. Human intelligence is not equal to the task, nor does it seem likely to be so in the future.

Chemical science has been responsible for the introduction of a number of hypotheses which have survived to the present day, and it may be worth while to look at them for a moment. The doctrine of atoms was not a chemical invention, but there is a vast difference between its use among Greek philosophers as a means of satisfying their desire to find a consistent explanation of the universe and its scientific application in the hands of Dalton as a means of explanation of the quantitative facts of chemical combination. There has been some discussion as to Dalton's personal attitude on this question, but there can be no doubt that those who did most to establish the doctrine attached no metaphysical importance to it, but used it frankly as an hypothesis to explain known facts and, above all, to predict new facts.

It is probable that throughout the nineteenth century it was a matter of comparative indifference to most scientific chemists whether atoms had a real existence. All that was important was that matter behaved as though it had an atomic structure, and that no fallacies

¹ From the presidential address, entitled "The Chemistry of Solids," delivered on August 31 at Southampton before Section B (Chemistry) of the British Association.

or errors were introduced by making such an assumption. The value of the atom to them was quite independent of any possible demonstration of its real existence. Gradually, as the conception of atoms and molecules was found to fit a larger and larger field of facts, confidence grew, and atoms came to be regarded as real, in the only sense in which the scientific experimenter can understand reality. Molecules, built up of atoms according to well-established laws, shared in this confidence, which was thoroughly justified by the remarkable concordance of the determinations of Avogadro's number, the number of molecules in the gram molecule of a substance, as arrived at by a number of totally independent methods.

The discovery of radio-activity, whilst enlarging the conception of the atom, has made it possible to isolate the effects of single atoms travelling at a high velocity, so that the impact of a single α -ray on a fluorescent screen produces a visible effect, and the counting of these rays, which are known to be charged helium atoms, corresponds perfectly with the original hypothesis. When the minuteness of the atom was realised, chemists cannot have dreamed that a day would come when the effect of so extraordinarily minute a particle could be perceived by the eye and even exhibited on a screen to an audience. No more extraordinary confirmation of the soundness of the theoretical views of the chemists of the early nineteenth century could have been received.

Next came the development of structural theory, with reference to organic compounds, associated with the names of Kekulé, Couper, Crum Brown, and Butlerow. Again the assumed arrangements of atoms in compounds were adopted in order to express the reactions of the substances, without reference to the real existence of the chains of atoms represented in the new formulæ. Within the last few years the study of the films of fatty acids and similar substances on the surface of water by Langmuir, Hardy, and Adam has shown that the properties of such films can only be accounted for by assuming the reality of those chains of atoms which served so well the purposes of the chemist, but seemed physically improbable. The examination of solid fatty acids by means of X-rays leads to exactly the same conclusion. The greatest triumph of structural theory, the hexagon formula for benzene, need only be mentioned in passing, since it is only a month or two since the celebration of the discovery of benzene by Faraday, when the wonderful chemistry of the aromatic compounds was eloquently described by Sir William Pope and Prof. Armstrong. Next came the generalisation known as the periodic system of the elements, due mainly to Mendeleëff and to Lothar Meyer, and finally the hypothesis of the tetrahedral arrangement of the atoms around a carbon atom, devised by van 't Hoff and Le Bel to account for optical isomerism. Modern X-ray methods show that the structure of crystals of the corresponding substances is fully accounted for by assuming that the benzene hexagon and the tetrahedral linking of carbon are actually present, and the interpretation of crystals has been made possible and unambiguous by the existence of so great a mass of fully established chemical data.

The point which I wish to make is that these hypo-

theses, of the chemical atom, of the molecule, of the chains and linkings represented in the graphic formulæ of organic compounds, of the hexagonal ring in aromatic substances, and of the tetrahedral carbon atom, were introduced without reference to any metaphysical conception of the nature of matter, and were independent of any dogma concerning reality. They were intended as working hypotheses, connecting and co-ordinating facts which had been discovered by the classical methods of chemical experimentation. That they have been confirmed by entirely independent physical means shows how sound was their foundation, and encourages us to suppose that the same methods which have served so well in the past may again be trusted to lead to new discoveries in the future.

The remaining example which I have mentioned, the periodic law, was regarded by many chemists as a convenient means of arranging the facts of inorganic chemistry, but was expressly stated to be only empirical, since a theoretical basis was inconceivable. The work of Moseley, the discovery of the radioactive elements, and the conception of isotopes, have shown the periodic classification to be the most fundamental thing in the chemistry of the elements, and the atomic number has been found to have greater theoretical significance than the atomic weight. Reference to isotopes reminds us that this discovery also was made by chemical means, although its investigation appears almost to have passed out of the hands of the chemist into those of the physicist, since the introduction of the positive ray method of analysis. It was the chemical work of Soddy, Russell, Fleck and Fajans, establishing the fact that two or more elements, differing in atomic weight but identical in chemical properties, could occupy the same position in the periodic classification, which opened up this new and extraordinarily important and interesting field of research.

The development of the theory of atomic structure, due mainly to Bohr, has necessarily affected modern views of chemistry. The theory was devised to explain the phenomena of radiation, and later proved to accommodate itself in a wonderful manner to those of chemical union, making use for the purpose of Werner's doctrine of co-ordination. In its new form it promises to do much to reduce to order the facts of inorganic chemistry, still so far behind the organic part of the science in the perfection of its logic. The static atom of Langmuir, now abandoned, played an important part in bridging over the gap between the planetary arrangement, chiefly suited to the explanation of spectra, and the present highly developed system.

Whilst recognising the immense value of the new ideas, may I once more venture to utter a word of warning? The modern student tends to specialise in his scientific studies at a very early stage, and, if introduced in detail to the new conceptions while still engaged in learning the elementary facts of chemistry, is likely to suppose that the facts depend on the theory, instead of the opposite being true. The danger may seem to be exaggerated, but it is nevertheless real. I would submit that the facts should be known to the student before he applies to them this interpretation, which may prove so fascinating as to distract his attention from the experimental basis of the science.

The Discharge of Electricity through Vacuum Tubes.¹

By Prof. R. WHIDDINGTON, F.R.S.

DISCHARGE tubes with cold electrodes and low gas pressure present a great variety of complex phenomena which, at the time of their discovery, were most difficult to explain. Many of these old difficulties remain, but some have been cleared away or are in process of being cleared away in the light of recent work. In any event, within the last few years sufficient new points of view have been put forward and fresh phenomena discovered to warrant recollection of the past and special notice of the present.

With the gas pressure in the neighbourhood of 1 mm. of mercury and the discharge passing along a straight cylindrical glass tube furnished with plane electrodes, the appearance shown diagrammatically in Fig. 1 is presented. For convenience we may consider the discharge under three headings.

1. *The cathode region*, comprising the softly luminous cathode glow, the Crookes' dark space and the negative glow.

2. *The anode region*, consisting of a very thin layer of light over the anode surface.

3. *The central region of the tube including the positive column* continuously glowing, sometimes striated, separated from the cathode region by the Faraday dark space and extending right up to the anode.

These are the usual, easily recognisable divisions of the discharge with cold electrodes and a steady applied potential of a few hundred volts.

Speaking generally, the current passing through the tube will be carried almost entirely by electrons and positive ions, negative ions being comparatively unimportant. Owing to the difference in nature of these two types of carrier, however, and their interdependence, important space charge effects within the tube and area charge effects on the walls are set up, which play an important part in determining the electric forces and thus the nature of the discharge. We shall outline these and other matters in what follows.

1. The Region of the Cathode.

The cathode is the seat of origin of the very speedy electrons—the cathode rays—which often possess a velocity little short of that given by the usual relation

$$eV = \frac{1}{2}mv^2,$$

where V is the potential difference between the cathode and the edge of the dark space—the so-called cathode fall.

The dark space edge is inexplicably sharply defined and is imagined to represent the region where there is not only ionisation by the cathode rays but also recombination resulting in light emission. This is probably bound up in the fact that the electric field in the dark space has a high value whereas in the glow the field is very much smaller.

This matter of the value of the electric field is of great importance in the theory of the discharge. Measurements, whether made by the much criticised probe method or by Aston's transverse cathode ray method, show that the axial field X increases linearly with distance from the dark space boundary to the cathode. Brose, by a most ingenious method based on

observations on the Stark effect in the weak light emitted from the dark space region, has recently shown that *very close* to the cathode there is a sharp drop in the electric field. This is shown in an exaggerated manner in Fig. 1. This state of affairs in the dark space is regarded as due to the space charge effects.

It was shown long ago by Schuster, Wehnelt and others by placing obstacles in the dark space that there was a "shadow" thrown both ways, so to speak, the supply of electrons from the cathode and the positive rays approaching thereto being simultaneously cut off. It was inferred that the main supply of electrons from the cathode arose somehow from the arrival there of positive ions originating in the edge of the negative glow. We conclude therefore that, since the speed of the ions is so much smaller than the electrons, there will be, on the whole, a concentration of positive

FIG. 1.—Diagrammatic representation of the regions in an exhausted tube, with, below, a curve showing the changes in the electric field in passing along the tube

electricity in the dark space. We should thus be able to obtain an expression for the variation of X by applying Poisson's law,

$$\frac{dV}{dx} = -4\pi\rho,$$

in much the same manner as in Langmuir's well-known application to the thermionic valve.

The form of the expression obtained, however, will clearly depend on the assumption made as to the distribution of positive electricity in the dark space. Assuming an impartial distribution of the positives in the dark space—an assumption incidentally not in accord with the generally accepted view of ion production outlined above—Sir J. J. Thomson deduces an expression for the electric field in accordance with the experimental results of Aston.

Very close to the cathode, on the other hand, the expression would scarcely be expected to hold, since here, production of electrons by ion bombardment is taking place, resulting in a negative space charge and a consequent lowering of the field. This brings Brose's experimental result into line.

It is interesting to note in passing that it is not an entirely straightforward matter to explain how electrons are produced at the surface of the cathode by positive ion impact. For although the whole energy of the approaching ion is adequate, this energy can only be handed over in part—and a very small part, a consideration which, when taken into account quanti-

¹ Substance of three Tyndall Lectures delivered at the Royal Institution on May 19, 26, and June 2.

tatively, leads to the result that insufficient energy to effect ionisation is actually available.

The most likely explanation appears to be that the ion on reaching the cathode captures an electron, radiates at the appropriate frequency, and it is this radiation which ejects from the cathode low speed electrons destined to form the cathode rays. We should expect on this view that the heating effect at the cathode would represent nearly the whole energy of the incident positive rays, an expectation in accordance with the facts.

2. The Anode Region.

Just as there is a jump of potential near the cathode in passing across the dark space, so there is an anode fall of potential.

The anode fall, however, appears to be capable of easy explanation. It is not at all dependent on the nature of the electrodes but only on the gas and on the current flowing. Moreover, as the current is diminished the anode fall rises to a constant value which approximates very closely to the ionisation potential of the gas.

We conclude, therefore, that the cloud of negative electrons near the anode produces this anode fall, and that at small currents its nature is such that single impact ionisation occurs at the anode surface, this ionisation taking place perhaps in a film of gas on the electrode. At high current densities the anode fall diminishes, probably because cumulative ionisation then takes place.

3. The Central Region of the Tube.

The positive column which occupies the central portion of the tube is in many respects the most puzzling part of the discharge. Separated from the negative glow by the Faraday dark space and extending right up to the anode, its character is usually independent of the length or shape of the tube; it is sometimes a uniform column of light, sometimes—particularly when the gas is impure—striated. The conductivity of this region is high and the electric force small.

It has usually been supposed that for the continuous positive column there is a copious supply of electrons moving with ionising speed under an electric field partly determined by the space charges and partly by the charges on the wall of the tube. It is clear that the electrodes themselves cannot contribute, directly, at all to this field.

The emitted light has been supposed to be due to ionisation and subsequent recombination, which latter process is encouraged by the small electric field—in contradistinction to the state of affairs in, for example, the Crookes' dark space. The striations have been supposed to be a repetition of the state of affairs near the cathode, the non-luminous spaces between the striations being the equivalent of the Faraday dark space.

It is an interesting fact, however, that even with the perfectly steady potential from a battery of storage cells applied to the tube, it is very usual to find that the current itself is regularly intermittent, a phenomenon which has been known for many years but has never been explained.

I pointed out recently (*Proc. Camb. Phil. Soc.*, 1924) that this effect is particularly marked in the case of the discharge through argon, and that if the tube be

made of quartz and a current of several amperes passed to produce a brilliant luminosity, then most beautiful effects are observed if the tube be viewed in a mirror rotating rapidly about an axis parallel to that of the tube. Fig. 2 is an untouched reproduction taken from an instantaneous photograph obtained in this way. It will be seen that the appearance presented is that of a number of straight, parallel equidistant lines inclined at an easily measurable angle with the horizontal. The heavy horizontal line is a superimposed photograph of the glowing tube viewed in the mirror at rest. The narrow vertical line on the extreme right of the equally spaced markings is a photograph, in the same spinning mirror, of a little mercury vapour lamp fed with alternating current of about 40,000 frequency from an oscillating thermionic valve.

Interpreted broadly, this photograph shows that, so far as the luminous character of the discharge is concerned, flashes of uniform speed follow each other at equal intervals of time down the tube moving from anode to cathode. Their velocity and frequency past

FIG. 2.

any point in the tube may be calculated from their inclination and distance apart.

When it is remembered that these discontinuities in the discharge occur with a steady applied potential and are practically independent of any capacity, inductance or resistance, included in the circuit, it will be seen that the phenomenon is well worth remark and further investigation. It is intended at the moment to give only a very general account and explanation so far as the available experimental evidence will allow.

In the first place—as might be expected on almost any reasonable theory—the velocity of the flashes increases as the gas pressure is reduced, being nearly proportional to $1/p$. For a given strength of electric field this is what is to be expected if the moving flash consists of or is associated with moving electrons or ions. The speed is, however, also determined in part by the strength—or rather average strength—of the current, increasing somewhat with greater currents. At the same time the frequency—indicated by the distance apart of the flashes—also increases as the velocity increases, in many cases, in nearly the same proportion.

A highly important fact which came out quite early in the experiments is that the emitted light, when examined with a spectroscope of high resolving power (a spectroscope fitted with a Fabry and Perot étalon), shows no signs of the Doppler effect. That is, when

the spectrum is viewed at right angles to and along the axis of the tube, there is no detectable change of wavelength in any of the lines suitable for examination. Had the sources of emission been moving with the speed of the flashes an effect should certainly be observable.

FIG. 3.

I think that an explanation (although another is possible) of this flash phenomenon may be based on a rather similar effect I chronicled in 1919 in the late *Radio Review*. If an ordinary thermionic valve con-

FIG. 4.

taining a trace of mercury be linked to a non-inductive circuit as in Fig. 3, then if the potential (V) applied to the grid be varied between certain limits, the current in the valve circuit oscillates at a frequency (n) such that n^2/V is constant. It was shown that the effect can be satisfactorily explained on the reasonable supposition that there is some particularly active electron-emitting point on the valve filament which, when bombarded by positively charged mercury ions, emits still more vigorously (whether by space charge neutralisation or by local heating is immaterial to the general idea); the result is that there are set up regular sequences of electrons flowing to the grid in a negligibly small time and positive ions produced in the region of the grid and falling back to the filament. The time taken by these positives in travelling from grid to filament determines the oscillation frequency. In the note referred to, it was

shown that a quantitative explanation along these lines is possible.

It would seem that a similar explanation might be made in the case of the flashes in the long discharge tube. The anode, on this view, would be the seat or origin of the flashes. We suppose a cloud of electrons round the anode; only those starting from a certain minimum distance will ionise at the anode surface. As soon as this occurs a sheet of positive ions will move away from the anode at a speed determined by the electric field, but the presence of this positive sheet constitutes a space charge which will so reduce the field in its train as to prevent further ion production; it therefore moves away as an isolated sheet of ionisation—to be followed in due course by a similar one produced in a similar manner. Why is not the Doppler effect observed? The suggestion is that the visible light emitted is not due to these moving ions but is a state of affairs produced by them. We must imagine that invisible radiation is given out which excites (possibly without ionising) the relatively immobile atoms of gas past which the radiating ions move.

There is some evidence, however, which it is not proposed to discuss here, in favour of a modified view of the ordinary discharge recently propounded by Günther Schulze. This investigator suggests that where a stream of electrons moving with high speed encounter and ionise (or excite) gaseous atoms, the spent electrons may produce a space charge. I merely wish to mention here that it is possible to give an alternative explanation along these lines but at the same time to point out that it is by no means impossible that both mechanisms operate, according to the conditions obtaining within the tube.

When the gas in the tube is pure it is usual to observe the appearance shown in Fig. 2, but after the discharge has passed for some time, there appear in the rotating mirror two sets of flashes; those at the anode end being much steeper, *i.e.* more slowly moving, than those at the cathode end. A reproduction of a photograph of this kind is shown in Fig. 4.

I believe this to be due to the presence of a little hydrogen. If the spectrum of the light emitted be

FIG. 5.—Two coarse-ruled gratings superimposed with lines slightly inclined to each other.

examined, it is found that near the anode the spectrum of hydrogen is strongly developed, while near the cathode it is absent or very weak. Now the slopes of the two sets of flashes are such as to suggest that the slow ones are due to argon ions and the fast ones to

hydrogen ions. This at once suggests a reason for the spectrum distribution just mentioned, for where the fast flashes occupy the tube, all or most available hydrogen will be taken up in the form of non-luminous ions and the radiation they emit will only have argon atoms on which to work. The hydrogen spectrum will therefore be weak or invisible.

So far we have been walking on fairly solid ground, but it is interesting to observe in conclusion that the definite experimental proof of the existence of these two sets of flashes through an impure gas may be made the basis of a somewhat speculative suggestion as to the origin of the familiar vacuum tube striations. We have only to suppose that in the impure gas there are two sets of flashes moving with different speeds and in simultaneous existence along the tube and we

get at once that if the velocities are related in a certain manner, continuous steady striations occur where the two sets cross. An example of this combination effect is shown in Fig. 5, which is a photograph of two coarse-ruled gratings with their lines slightly inclined to each other. The edges of this photograph clearly show the lines of the two gratings separately and the central part where they are superimposed. The horizontal equidistant bands in this superimposed area are parallel to the shorter diagonals of the parallelograms produced by the intersections of the two sets of mutually inclined lines, and, according to our speculation, would represent the striations as seen in the rotating mirror. Further experiments, however, must be performed before anything more definite can be put forward.

A Cotton Research Station for the British Empire.¹

IT has long been a weak point in the scientific investigation of the agriculture of the British tropical dominions that we have had no stations where problems that are fundamental and underlying, affecting all tropical countries alike, could be attended to: Local departments of agriculture are necessarily and rightly occupied with local questions, and authorities might look askance at such a department if it were to devote itself, for example, to the fundamental problem of the connexion between lint characters in cotton and spinning qualities.

This defect in our organisation is now to be removed, so far as cotton is concerned, a forward step of great importance having been taken by the Empire Cotton Growing Corporation, which, with the express aim in view of the solution of problems of this nature, has decided to open in Trinidad a cotton research station, near the Imperial College of Tropical Agriculture. The station is to be provided with a first-rate staff, and well endowed with funds, so that great results may be expected from this far-seeing enterprise.

"It is intended to investigate there the cotton plant in all phases of its growth and under rigorously controlled conditions, so that it may be possible to ascertain and to estimate the importance of the several factors which contribute to the final result." In other words, it is in no sense intended as a local station for the investigation of problems which are of local origin and can only be solved under corresponding local conditions, nor is it intended as a place for the breeding of pure-line seed upon a large scale. Such seed, with various special characteristics, will indeed be produced, but when it is introduced into other places, the effects of acclimatisation (at present not understood) will come in, and it is for each individual country to produce from the seed the cotton that is best adapted to its local conditions. Much labour in breeding will thus be saved to the local workers, for they will start from seed of known genetic qualities. The new station will not relieve the local agricultural departments from the necessity of scientific work upon their local problems, but will provide them with better fundamental knowledge upon which to base their investigations.

Since it was decided to establish the station, a strong committee has been at work considering the claims of

various places in the warmer parts of the British Empire, and at last, by a process of gradual elimination, decided that Trinidad was the most promising. Prof. J. B. Farmer and Mr. L. G. Kilby (secretary of the Corporation) were then sent out to report in more detail, and as a result Trinidad has been finally selected.

In his preface Dr. W. L. Balls directs attention to the fact that it was the late Mr. J. W. McConnell (first chairman of the Council of the Corporation) who was chiefly responsible for the achievement of this result—a result which even ten years ago would have been considered Utopian.

Trinidad is suited, in the neighbourhood of Port-of-Spain, to the cultivation of cottons of many different kinds, but has not proved commercially successful in their growth, so that the cottons upon the station will not be liable to hybridisation with others growing near by—an important advantage. It is easily accessible from England, and from the other countries of the American continent where cotton is cultivated on the large scale. It has a good and healthy climate, and the site chosen is near to the capital town, while it is also near to the Imperial College of Tropical Agriculture, thus placing its staff in close contact with the workers in the latter, and with the facilities there provided. This is another advantage of great importance to both parties, especially as a good many of the future employes of the Corporation are trained at the College, and will thus have the station near at hand, and be in a position to get upon friendly terms with the staff, from whom they will be able to get useful hints in their work.

The site is an area of sixty acres, about one-third of which will be planted in cotton every year, with cane as a rotation. It is proposed that work be begun by the appointment of a geneticist and a plant physiologist, each with a competent understudy and the needful assistance, including frequent study-leave and travel. The management and general direction it is proposed to entrust to a local advisory committee of two—Dr. H. Martin Leake, Principal of the Imperial College, who has done much research work upon cotton, and Mr. W. Nowell, Assistant Director of Agriculture in Trinidad, well known for his work in mycology, etc. These gentlemen will act in their private and not in their official capacity. It is also hoped to arrange for exchanges of staff with the Shirley Institute of the British Cotton Industry Research Association.

¹ Summary of a Report to the Empire Cotton Growing Corporation, by Prof. J. B. Farmer and Mr. L. G. Kilby, with a foreword by Dr. W. L. Balls (London, 1925).

Obituary.

PROF. F. R. JAPP, F.R.S.

FRANCIS ROBERT JAPP was born in Dundee on February 8, 1848, his father being the minister of the Catholic Apostolic Church in that city. His early academic training gave little indication of his ultimate career, for after graduating in arts at the University of St. Andrews he entered the University of Edinburgh as a student of law in 1868. Ill-health, unfortunately, soon led to an interruption of these studies and to a fairly long period of foreign travel and residence, mostly in Germany, and it was not until the autumn of 1873 that Japp definitely settled down to the study of chemistry in Bunsen's laboratory at Heidelberg. He completed his curriculum at that university by graduating as doctor of philosophy in 1876, and afterwards proceeded to Bonn, whither the fame of Kekulé attracted chemical pilgrims from all parts of Europe. In his Kekulé Memorial Lecture, delivered before the Chemical Society in 1898, Japp paid eloquent tribute to the inspiring genius of this great chemist. While in the Bonn laboratory, Japp worked more especially under Schultz and Anschütz, and papers were published jointly with each of these investigators.

In 1878 Japp returned to Great Britain, and after working for a short time in Crum Brown's laboratory in Edinburgh he became research assistant at the Normal School of Science, South Kensington, under the late Sir Edward Frankland. At the reorganisation of the Science Schools in 1881 he was made assistant professor in the department of chemistry, and this post he continued to hold until his appointment in 1890 to the chair of chemistry in the University of Aberdeen, as the successor of Thomas Carnelley. During his tenure of the London post, Japp devoted himself with great industry and enthusiasm to the prosecution of research in organic chemistry, and in the decade 1880-1890 he published, either in his own name or conjointly with his pupils, about forty papers dealing largely with phenanthraquinone and other diketones and their derivatives. This activity in research was recognised by election into the Royal Society in 1885, and by the award of the Longstaff medal of the Chemical Society in 1891. For six years, moreover, he acted as foreign secretary of the Chemical Society, of which body he was later a vice-president for two periods.

At the time of Japp's arrival in Aberdeen the reconstruction and extension of the chemistry department were overdue, but for several years the work had to be carried on in the old, ill-ventilated, badly lighted laboratories. In spite of this, Japp, who was pre-eminently an investigator, contrived to prosecute and encourage research work, and it was perhaps his chief service to the northern university that he fostered the spirit of original investigation and inquiry in a none too favourable environment. During his tenure of the Aberdeen chair, covering the period 1890-1914, about forty memoirs emanated from the chemical laboratories there.

The character of this, as well as the earlier research, was such as to attract the notice mainly of specialists; but Japp's address on "Stereochemistry and Vitalism," delivered in 1898 in the capacity of president of the

Chemistry Section of the British Association, made a much wider appeal, and gave rise to an animated discussion in the columns of NATURE. The thesis put forward in the address, and defended with much suggestiveness and resource, embodied a development of Pasteur's view that "the production of single asymmetric compounds or their isolation from the mixture of their enantiomorphs is the prerogative of life. Only asymmetry can beget asymmetry."

This sketch would be incomplete without some reference to the very wide scope of Japp's interests. Primarily a chemist, he possessed marked literary, artistic, and linguistic talent, and the British Association address already mentioned furnishes ample evidence of his broad philosophic outlook and of his well-stored mind. An accomplished linguist, he was familiar with much of the best in the literatures of Germany, France, and Italy, as well as of his own country, while on the artistic side he was a musician of knowledge and taste.

After relinquishing the Aberdeen post, Japp lived quietly in retirement in London until his death on August 1 last. Latterly a semi-invalid, he was dependent on the unremitting care and attention of the widow and two daughters who remain to mourn his loss.

J. C. P

PROF. OTAKAR KUKULA.

THE Charles' (Bohemian) University of Prague lost on August 11, at the relatively early age of fifty-eight years, one of its most eminent professors, namely, Prof. O. Kukula, professor of surgery, director of the first surgical clinic, and at the same time Rector Magnificus of the University. Prof. Kukula's clinic was equipped in the most modern way, and he was in close touch with internal chemical as well as biological methods of investigation, so that his chair was a model of its kind. As a surgeon he was unsurpassed, being able to carry out surgical operations of the most difficult and delicate kind with the greatest ease and calm. He not only studied all known good methods of operation, but also introduced many new and the most difficult ones, and he was well known for this in scientific circles abroad as well as at home.

Prof. Kukula published in Bohemian, French and German more than forty scientific papers, of which only those on stones in the bladder and on the surgery of the kidneys need be mentioned. His great work, "Pathology and Therapy of the Inflammation of the Appendix," is a remarkable monograph, finding its equal only in the work of Kelly.

Prof. Kukula was a member of the Bohemian Academy and of many foreign scientific societies, and he was also the founder and president of the Czechoslovak Automobile Club. He rendered great services to the Serbs in the war with Turkey and was decorated with the highest Serbian orders.

BOHUSLAV BRAUNER.

WE regret to announce the following deaths:

Prof. E. H. Barton, professor of physics, University College, Nottingham, on September 23, at sixty-six years of age.

Don Luis Cubillo y Muro, director of the Geographic Institute of Spain and president of the Spanish National Committees of Geophysics and of Astronomy, on July 10.

Current Topics and Events.

PARTICULARS of the fifth Congress of Industrial Chemistry, organised by the Société de Chimie Industrielle, are now available. On October 4 there will be an official reception, followed by a musical soiree, in the Hôtel Majestic, Paris. The following day, the Minister of Public Instruction will open the congress in the Conservatoire National des Arts et Métiers, where the international exhibition of the decorative arts is being held, and where all the subsequent meetings will be held. At the opening ceremony, M. L. Guillet will give an address on the rôle of French science in metallurgy. Sir Robert Hadfield is contributing a valuable paper on French scientific investigators and institutions and on some unsolved problems relating to manganese steel. October 6 will be devoted to conferences on fuels and on metallurgy; October 7 to meetings of the sections, and a banquet in the evening; and on the final day, October 8, the presidents and recorders will meet, and an address on the refining of mineral oils will be given by Prof. H. T. Waterman, of the University of Delft. The remainder of the week will be spent visiting the exhibition, the Renault automobile works at Billancourt, the dyeworks and vanneries at Saint-Denis, or, alternately, to an excursion to Grenoble, where the international water-power exhibition will be in full swing.

ON Sunday, October 11, the centenary of Chevreul's researches on the animal fats will be celebrated in the amphitheatre of the Natural History Museum, Paris, and the proceedings will be honoured by the attendance of the President of the Republic and of the President of the Council of Ministers. In the evening there will be a reception of the foreign delegates. It was in the same place that the anniversary of Chevreul's hundredth birthday was celebrated on August 31, 1886, by the unveiling of a statue to him. On that memorable occasion, Frémy, who followed Chevreul as director of the museum, delivered the principal oration, in the course of which he aptly quoted the saying of Malebranche: "Il faut tendre à l'infailibilité sans jamais y prétendre"; and no less happily, the Minister of Public Instruction quoted the remark which Dumas, the chemist, had made to Chevreul some fourteen years before: "Your work has been the only occupation which has never fatigued you." Chevreul's achievements as an investigator, and as an eclectic philosopher, are inscribed for all time on the pages of history, and on October 11, not only chemists but all followers of science in Great Britain will do silent homage to his memory.

FULLER details of the wreck of the airship *Shenandoah* are now available. The explanation, attributed to a German expert, that relief valves had been removed from nearly half the gas bags, and that their absence would cause disruption, has been dismissed by the U.S.A. official investigator. He attributes the accident to structural failure under the exceptional stresses imposed by a severe local atmospheric disturbance. Controversy is now directed to the

question of effective meteorological service for aeronautics. The reports of the U.S.A. stations are edited by the Weather Bureau of the Department of Agriculture. Information is received daily by telegraph and embodied in the British chart of weather in the northern hemisphere, which shows a shallow depression moving across the great lakes along the line Winnipeg-Chicago-Washington on September 2, 3 and 4. The U.S.A. daily chart, since received in England, amplifies the information and indicates local thunderstorms along the fronts of the disturbance, without suggesting the extreme severity of the conditions developed along the front of the disturbance. The *Shenandoah*, travelling westward from New Jersey on September 2, met the front of the disturbance on the morning of September 3, near Cambridge, Ohio, roughly half-way between Washington and Chicago, and was destroyed. Meteorologists will be of the opinion that ample material for serious warning was available but that the liaison service was inadequate. More precise information, such as an hourly local report from the nearest meteorological stations, would have been required to warn the airship fully of the rapid increase in the severity of the conditions locally. The fact remains that a continental area exposed to numerous severe and sudden storms is not specially suitable for airship services, and the wider question is inevitably raised as to whether the airship is not altogether too fragile a structure on which to place hopes of regular commercial transport services over thousands of miles of land and sea.

THE Imperial Social Hygiene Congress will meet at Wembley on Monday, Tuesday, and Wednesday of next week. The Congress is being organised, as last year, by the British Social Hygiene Council, which at that time was known as the National Council for combating Venereal Diseases. The president is Sir Auckland Geddes, and the patrons include Mr. L. S. Amery, Mr. Neville Chamberlain, Viscount Willingdon and the High Commissioners of the Dominions. In an opening address Mr. Amery will discuss the Imperial aspect of social hygiene. He will be supported by the High Commissioners, and reports will then be received on the administrative, military, and naval position with regard to venereal diseases within the Empire. The afternoon programme includes a statement by Sir Claude Hill, director-general of the League of Red Cross Societies, on methods of health propaganda in Europe and the Far East, and a paper by Dr. H. M. Hanschell on the problem of venereal disease in relation to race and climate. The chief debates on Tuesday will be on the position with regard to venereal disease in Great Britain and self-governing dominions, to be opened by Mr. Neville Chamberlain, and on social hygiene in relation to the mercantile marine, while there will also be a discussion on venereal disease and emigration. The concluding day on Wednesday will be devoted to the consideration of the problem of venereal disease in India and in the Colonies and Protectorates and mandated territories. During the course of the

meeting a number of films dealing with the work of the Council will be exhibited.

WE see by a letter in the *Veterinary Record* that Prof. Hobday is this week taking over to Holland a party of veterinary surgeons and others with the object of showing them that, contrary to general opinion, England in its treatment of such animal products as milk and meat very greatly lags behind many of the continental countries. He has secured the co-operation of a considerable number of veterinary public health officials, and the party, which leaves on Saturday, will include amongst its representatives a number of delegates from those who for years past have been attacking what is generally known as the "decrepit horse traffic." His interest is primarily, according to the statement issued, in the fact that Holland possesses laws (and enforces them) which make it practically impossible for unsound food to be placed on the market. The programme is an interesting one. The party will have every opportunity of seeing the horses as they embark and as they disembark. The members will see the application of the Mallen test, which is compulsory by law, for glanders. Dr. Laurens is enabling them to visit the Serum Institute at Amsterdam, and this visit will be followed by one to a large hygienic dairy at Hillegom, where the cattle are all milked by machinery. On the following day there will be an inspection of the well-known dairy herd of the Netherlands Herd Book Association. The Veterinary School at Utrecht and the Amsterdam abattoir (one of the most up-to-date and modern buildings in existence), with its splendidly organised system of veterinary supervision and its humane methods of killing, will be inspected. On Tuesday, through the courtesy of Dr. Bonner, the director, there will be an inspection of the Cancer Institute and of the Amsterdam zoo and aquarium, each of which are amongst the most celebrated in the world. The visitors to Amsterdam will be accompanied by Dr. J. A. Klauwers, the District Veterinary Inspector, who is responsible for the carrying out of the law concerning the contagious diseases of animals in Amsterdam and the surrounding district.

THE British Institute of Philosophical Studies, which was formed in the early spring of this year, has recently issued a syllabus of the initial courses of lectures to be given under the auspices of the Institute. The lectures, which are ultimately intended to cover every branch of philosophy, are open to all persons interested in the subject who have registered and paid the necessary fees, 1*l.* 5*s.* for a term's lectures, and 2*l.* 2*s.* for the whole course of two terms. The courses of lectures announced for the forthcoming term are on "Problems of Philosophy," by the Hon. Bertrand Russell, on Wednesdays at 5.30, at the London School of Economics, beginning October 7; on "Present Tendencies in Political Theory," by Mr. H. J. Laski, on Thursdays at 5.30, at the Royal Anthropological Institute, 52 Upper Bedford Place, beginning October 8; and on "Psychology," especially tendencies and controversies in modern psychology, by Prof. T. H. Pear, on Fridays at 5.30, also at the Royal Anthropological Institute. Copies of the

syllabus, which contains further announcements for the Lent term, can be obtained from the director of the Institute at 88 Kingsway, W.C.2, to whom all inquiries relating to the work of the Institute should be addressed.

THE centenary of the opening of the Stockton and Darlington Railway occurred on September 27, and to commemorate this important event a special exhibition has been formed in the Science Museum, South Kensington, as a supplement to the general railway groups of the land transport collection. This supplementary collection comprises many objects from this collection relating to the Stockton and Darlington Railway, together with a number of new objects, documents and pictures, bearing on the history of railways, which have been lent for the occasion by the railway companies and by private contributors. A catalogue of the collection has been prepared, the contents being classified under the headings—history, construction, locomotives, rolling-stock and working. The earliest books and other documents relating to the Stockton and Darlington Railway are shown, including George Stephenson's original report of 1822, and many original letters, portraits, prints and medals are exhibited in the historical section, besides early railway plans and specifications, drawings of works of construction and buildings, and examples of permanent way. A few models and numerous drawings of locomotives are also included, with various items connected with rolling-stock. Railway working is illustrated by signals and signalling apparatus, time-tables, tickets and ticket printing machines. The exhibition, which will be found on the ground floor of the new Science Museum building, will remain for several weeks.

IN consequence of the rearrangement of the collections in the different museums at Hull, as a result of the opening of the New Commercial Museum, one of the galleries in the Natural History Museum, Albion Street, has been entirely rearranged and devoted to the exhibition of osteological preparations, including a representative series of skeletons and skulls of various mammals and birds, the larger mammalia (whales, etc.) and fishes being exhibited in the Museum of Fisheries and Shipping in another part of the town. One side of the new gallery is devoted to human skeletons of various ages, and include bronze age, iron age, Roman, Anglo-Saxon and medieval skulls, the Museum possessing a remarkably fine series in this respect. There are also human crania from various parts of the world and plaster casts of all the really important prehistoric skulls at present available. In addition, there are copies of the well-known series of restorations of different types of prehistoric man, the originals of which are in the Museum of Natural History, New York.

A MESSAGE from the Dublin correspondent of the *Times*, which appeared in the issue of September 23, announced the appointment of Dr. Walther Bremer as Keeper of Irish Antiquities in the National Museum at Dublin. This appointment has been vacant since the resignation of the late Mr. E. C. R. Armstrong at the end of 1922 under the arrangements for the retirement

of Civil Servants made by the Irish Government. Dr Bremer is honorary professor of prehistoric archaeology in the University of Marburg, Germany, and has a high reputation on the continent as a prehistoric archaeologist, especially in connexion with the neolithic period and with the antiquities of Great Britain and Ireland. He has contributed a number of articles to the "Reallexicon der Vorgeschichte," published by Messrs. Gruyter, of Berlin. During the War he was a prisoner in England, but was released on parole and devoted himself to archaeological research.

DR G. C. CLAYTON, M.P., and Prof. H. C. H. Carpenter, F.R.S., have been appointed, by Order of Council dated September 16, to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

IN honour of the founder of the British Science Guild, Sir Norman Lockyer, the Council has established an annual Norman Lockyer Lecture, one of the objects of which is to direct the attention of the public to the influence of science upon human progress. The first lecture will be given by Sir Oliver Lodge, on Monday, November 16, 1925, at 4 P.M., upon the subject of "The Link between Matter and Matter." Lord Askwith, president of the Guild, will be in the chair, and the lecture will be delivered in the hall of the Goldsmiths' Company (by kind permission of the Master and Court of Assistants of the Company). Tickets of admission may be obtained on application to the secretary, British Science Guild, 6 John Street, Adelphi, London, W.C.2.

DURING the forthcoming winter, Mr. H. V. Garner, the guide demonstrator of the Rothamsted Experimental Station, Harpenden, will be able to give a few lectures to Chambers of Agriculture and Horticulture, Farmers' Clubs, Farm Workers' Associations, Agricultural Societies, etc., on the Rothamsted experiments in regard to artificial manures and their use on the farm, practical lessons from recent field experiments, profitable improvement of grass land, chalking and liming, and similar subjects. For students' societies and similar bodies, lectures can be arranged dealing with the planning and carrying out of field experiments, factors in soil fertility, etc. No fee will be charged for Mr. Garner's services, but any association engaging him would be expected to defray his travelling expenses and to make such

arrangements for the lecture as may be necessary. All communications regarding lectures should be addressed to the Secretary, Rothamsted Experimental Station, Harpenden.

SIR CHARLES SHERRINGTON, president of the Royal Society, will give the introductory address at the opening of the London (Royal Free Hospital) School of Medicine for Women (University of London), on Thursday, October 1, at 3 P.M.

THE new price list of fine organic chemicals issued in August by the British Dyestuffs Corporation, Ltd., includes indicators, microscopic stains, medicinal and photographic chemicals. Of special interest is the wide range of microscopic stains, produced by standardised methods and tested for purity both in the laboratories of the Corporation and independently. Information on a number of the substances can be obtained from separate booklets issued by the Corporation.

THE Oxford University Press announces the early publication of "The Surface History of the Earth," by Prof. J. Joly. The work is intended for the general reader with scientific interests and for students of geography and geology, and deals with the forces which have moulded the earth's crust.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned. In the Royal Aircraft Establishment, South Farnborough, Hants—A scientific assistant primarily for work in the aerodynamic section; two junior scientific assistants, one primarily for mathematical and experimental work on the stability and control of aeroplanes, and one for wind tunnel experiments, and three junior scientific assistants, respectively primarily for elasticity research, for problems arising in connexion with high altitude flying, and for work in connexion with indicating and recording instruments and similar apparatus—The Superintendent (October 13). A scientific assistant primarily for research in connexion with electrical ignition appliances—The Superintendent (October 20). A lecturer in chemistry at Armstrong College, Newcastle-upon-Tyne—The Registrar (October 17). A director and curator of the Harris Art Gallery and Museum, Preston—The Town Clerk, Town Hall, Preston (October 31). A research chemist at the new central research laboratory of the Colonial Sugar Refining Company, Sydney—Parbury, Henty and Co., 20 Eastcheap, E.C.3.

Our Astronomical Column.

BROOKS' PERIODIC COMET—As other observers failed to find any comet close to the place announced by Prof. Tcherny, fears were expressed that the news of the detection of Brooks' comet might be erroneous. A further telegram from Russia, transmitted by the I. A. U. Bureau, Copenhagen, makes it clear that the discovery is correct, but that Tcherny's first telegram gave incorrect position and magnitude. The following two positions are communicated:

	Univ. T.	R.A.	S. Decl.	Mag.
1925 Sept.	9 ^d 19 ^h 33 ^m 12 ^s	23 ^h 23 ^m 12 ^s	1° 49' 31"	13.1
	24 18 57.9	23 18 6.7	4 2 54	12.5

The observers are MM. Albitsky and Shain. These observations indicate that Dubiago's predicted date

of perihelion needs a correction very close to -6 days, his other elements being near the truth.

The following ephemeris for α has been deduced on this assumption.

	" R.A.	S. Decl.	log r	log Δ
Oct. 2.	23 ^h 16 ^m 19 ^s	4° 57'	0.278	9.965
10	23 15 39	5 48	0.276	9.977
18	23 16 35	6 25	0.274	9.993
26	23 19 22	6 46	0.273	0.013

The comet should be observable for some months. It is the fourth periodic comet observed this year, the others being Tempel (2), Wolf, and Borrelly. Faye's and Schorr's comets have also been looked for, but unsuccessfully as yet.

Research Items.

A SURVIVAL OF THE "THAMES PICK."—*Man* for September contains a note by Mrs. M. E. Cunnington on a "Thames Pick" found on a ledge or shelf in the chalk side of a pit-dwelling in Casterley Camp, Wilts. The flint is of a pale bluish-grey, the unground sharp nose shows no sign of use, and the whole surface is sharp and rough to the touch as if newly made, as it must have been when buried in the pit. The "Thames Pick" type of implement is usually held to be of late palæolithic or early neolithic date. In the present instance, however, it is recorded that it was found with three skeletons, two adult and one of a child, and under one of these were the remains of an iron brooch with a spiral spring of La Tène type, and under the child's skeleton was a second fragment of iron which was possibly the bow of another brooch. Pottery of a poor quality was also found which, taken in conjunction with the flint implement, might have led to an attribution to the Neolithic Age had it not been for the presence of iron. It is, however, clear from this find that implements of this type continued to be manufactured in Britain until well into the Iron Age.

PHYSICAL ANTHROPOLOGY OF THE HOS OF KOLHAN.—Mr. D. N. Majumdar has recently published several studies of the Hos or Kols and their culture. Of four in the current issue of the *Journal and Proceedings of the Asiatic Society of Bengal* (Vol. xx, N.S., Pt. 5) one deals with their physical characters, as shown in 10 measurements of 200 individuals which are given in a series of tables. They are short of stature, of dark complexion, with short, broad, and flat noses, small dark eyes, wavy to curly hair, beard or moustache being absent. The complexion varies from sooty black to dark brown. Fair Hos are occasionally encountered, but this is to be attributed to admixture with Rajput traders. The lips are medium, and slight prognathism is noticeable. The average cephalic index is 75.5, but 63 per cent. were dolichocephalic, 47 per cent. mesocephalic, and 12 per cent. brachycephalic. Cases of artificial deformation were noted. The highest nasal index was 91.1, the lowest 74.6. The average stature is about 161 cm., the lowest individual measurement being 158.2 cm., and the highest 170 cm. The arm's reach is proportionate to the stature, ranging from 166.6 cm. to 173.5 cm. Tattooing, formerly practised, has fallen out of favour, but where in use it is only on the fore-limbs, and especially the right hand. If a woman does not tattoo she commits a sin, as she takes nothing to the next world but these marks on her limbs.

THE BOSKOP SKULL.—Mr. W. P. Pycraft, who undertook to examine and report on the calvaria found at Boskop, Transvaal, in 1913, has contributed to the *Journal of the Royal Anthropological Institute*, Vol. LV., Part 1, a discussion of the conclusions at which he himself and Dr. H. S. Haughton, assistant director of the South African Museum, have arrived. Mr. Pycraft's reconstruction gives length 205 mm., breadth 150 mm., auricular height 125 mm., basibregmatic height 137 mm., cranial capacity probably 1717 c.c. In all its salient features the skull shows a likeness to the Bushman skull, but it is also comparable with the "Strandlooper" and the Cromagnon. The contours of the Strandlooper and Boskop skulls are almost identical except in the greater height of the latter. The Strandlooper stands midway between the Boskop and the Bushman skulls. Boskop Man is also genetically related to Cromagnon Man, the conclusion being that he would appear to be a derivative of Cromagnon Man and the progenitor of the

Bushman. It is therefore suggested that the proto-Bushman, *i.e.* the Boskop Man, arose out of the Neanthropic flux which gave rise to the Grimaldi people and the Cromagnards, the Australo-Dravidians and Rhodesian Man, the common stock from which all were derived being the smooth and "beetle-browed" Palæanthropic peoples. The apparently somewhat sudden appearance of the Neanthropic peoples is probably fictitious.

THE FLOODS OF THE NEVA.—The tendency of the lower Neva to inundate part of Leningrad has been a serious problem since the foundation of the town. It has been explained by river flooding due to precipitation, banking of the river flow by winds, and changes in the level of Lake Ladoga. In an article entitled "Les Crues de l'embouchure de la Neva" in *Matériaux pour l'étude des calamités* for April-June 1925, Dr. E. P. Pouichet shows that the main cause is a southerly and south-westerly gale in the southern part of the Baltic. This forces the water into the Gulf of Finland, especially since the free passage into the Gulf of Bothnia is obstructed by the Åbo and Åland archipelagoes. In the narrow and shallow Gulf of Finland the waters are heaped up, if the westerly winds persist, and overflow the tidal reaches of the Neva. If the westerly winds give way to northerly or north-westerly winds, the floods rapidly subside, and indeed may not reach dangerous proportions. Dr. Pouichet gives synoptic charts showing the meteorological conditions on the occasion of several serious floods, and describes the system of warning instituted some years ago and improved by the existing government in Russia. He discusses the possibility of protective works, but concludes that their cost would be prohibitive.

RAIN AS A CAUSE OF SPOTTING OF FOLIAGE.—Field observations having led to the conclusion that spotting of the foliage in apple trees in the wet season of 1924 was associated with the abnormal rainfall, Messrs. C. E. T. Mann and T. Wallace, of the Horticultural Research Station at Long Ashton, proceeded to examine the effect upon the foliage of these trees of temporary immersion in distilled water. As somewhat similar blotches appeared on these leaves, and as analysis showed that the distilled water was leaching considerable quantities of potash out of the leaves, the experiments were continued and showed that a variety susceptible to this spotting in the field, Cox's Orange, lost no less than 64 per cent. of the total potassium in the leaves after 24 hours' immersion in the water, whilst a variety resistant to spotting in the field in a similar experiment lost only 12 per cent. in the 24 hours. In view of their experimental results with varieties of different susceptibility, as recorded in the *Journal of Pomology*, vol. iv, pp. 146-161, there seems little doubt that the conclusion drawn from the field observations was justified, that rain was responsible for the spotting of the leaves noted in this particular season. It would also seem that the action of the rain water is associated with this little suspected capacity it has for leaching considerable quantities of soluble substances, including potassium compounds, out of the foliage of the plant.

CREAMING OF SPRAY FLUIDS.—Rowland Marcus Woodman continues his investigation of the fundamental physics and chemistry of spray fluids in the *Journal of Pomology and Horticultural Science*, vol. iv, pp. 184-195, with an interesting discussion of the difference between the "cracking" of an emulsion,

i.e. a mass separation of the two liquid phases, and the "creaming," in which a stable emulsion, containing practically the theoretical amount of the disperse phase when present in spherical droplets packed as closely as possible, separates itself by creaming from the excess of the continuous, and in this case denser, solvent phase. He points out that cracking and creaming are very different and that they are not necessarily favoured by the same conditions; furthermore, in practice with spray fluids, the danger is creaming. As a result of creaming a paraffin wash may be pumped on to foliage, the bulk of which is too dilute to be effective, whilst the remainder, the cream, may be so concentrated as to do damage. Mr. Woodman discusses the factors that facilitate creaming; he shows that the farmer is justified in his traditional view that a wide pan favours rapid creaming, a fact which is to the disadvantage of the sprayer, whose concoction is usually mixed in wide tubs on the farm. The author analyses the methods available to retard creaming, and gives his reasons for selecting as the most practical that of bringing both liquid phases nearer to the same density. He describes some very successful results obtained by means of cresols added to paraffin oil emulsions with this end in view. Altogether this paper seems a very satisfactory example of pure science in the service of horticulture. Mr. Woodman is working at the Horticultural Research Station, University of Cambridge.

PLIOCENE CLIMATE OF NORTHERN EUROPE.—Some deductions regarding the climatic conditions of Pliocene times in Iceland have been drawn by Gudmundur G. Bárðarson from his study of the mollusca in the deposits of that age, estimated at about 700 metres in depth, at Tjornes (*Det Kgl. Danske Videnskab. Selskab., Biolog. Medd.*, 4, 5, 1925). He finds that the remains of mollusca associated with warm-temperate seas occur chiefly in the older shell-bearing zones. These suggest climatic conditions similar to those of south and west Norway, or possibly of the British Isles. But during the period of the accumulation of the Pliocene deposits there was a gradual deterioration in temperature, for the southern forms of mollusca give place in the upper beds to an immigrant northern or arctic fauna, closely related to the molluscan fauna now existing on the shores of the North Atlantic. The Icelandic forms show, as geographical proximity would suggest, a closer relationship to the present-day fauna of America than do the fossils of the English Crag series, which the author considers to have been formed about the same time. There is no indication in the Tjornes beds of a sea-temperature on the coasts of Iceland colder than that of the present day.

PHYSIOGRAPHY OF THE SHIRÉ VALLEY—A paper on the physiography of the Shiré valley by Dr. F. Dixey has been published by the geological survey department of Nyasaland. Dr. Dixey shows that an examination of the uplands bordering the Shiré Rift exhibit several additional branches of the main rift of considerable importance. Parallel with the Upper Shiré Rift, which runs N.N.E., is the long depression that includes the Upper Lujenda, Lake Chilwa, and the plains to the south. Parallel with the Lower Shiré Rift, which runs N.N.W., is a depression that extends from the southern end of Lake Nyasa, and includes Lake Malombe, part of the Upper Shiré Rift, Lake Chilwa, and the eastern foot of the Mlanje mountains. These intersecting rifts thus account for the position of Lakes Chilwa and Malombe and the upland area of the Shiré highlands. Dr. Dixey discusses the succession of the faulting that caused these features, which he believes took

place at several distinct periods separated by appreciable intervals.

CLIMATE OF GLASGOW.—The Meteorological Office, Air Ministry, has published in Geophysical Memoirs, No. 23, a memoir on "The Climatology of Glasgow," by Prof. L. Becker, professor of astronomy in the University of Glasgow (M.O. 254 C., H.M. Stationery Office, 1925, 10s net). Weather observations recorded at the Glasgow University Observatory since 1843 are dealt with; since 1868 the observations have been taken in association with the Meteorological Office. In the course of time much building has sprung up round the Observatory, and it seems quite possible that some of the weather changes may be due to artificial causes rather than to natural change of climate. The author attributes the lines followed in the discussion as "suggested by inquiries from engineers and lawyers." The charm of the work is the diversity of inquiry to which the several elements are subjected. The statistics are said to have been ready for publication since 1908, when forty years were available, but funds for publication were lacking. Barometric pressure, temperature, humidity, sunshine, cloud, visibility, and wind are analysed, and to take temperature as an illustration, the examination consists of more than twenty tables. In addition to the normals for the several months and years, the diurnal changes and 5-day means, there are tables of excesses and deficiencies in mean temperature relative to the average, number of warm days and warm nights in summer, number of cold days and cold nights in winter (these are given for each year), number of periods of warm weather in summer and cold in winter. An examination of the discussion has suggested the wish that it might be possible to submit the Greenwich Observatory records to similar diversities of inquiry. There the system and uniformity of observation, together with the relatively open position, would probably allow a change if ascertained to be attributed to cosmical effects.

MAGNETIC DECLINATION AND THE MAGNETISATION OF ANCIENT LAVA.—The lava flows of Mount Etna have been studied by M. R. Chevallier, who shows that it is possible to determine the magnetic declination at the time the lava solidified by observing the direction in which it is now magnetised (*Annales de Physique*, July-August). Although the actual field in which solidification took place was, in general, disturbed by the presence of other masses of magnetised lava, it appeared possible, by taking the mean between the directions obtained from a number of specimens chosen from points in a given lava flow where there has evidently been no displacement of the lava after solidification, to obtain a satisfactory value for the declination at the time of solidification. The values deduced in this way from the lava streams of 1669 and 1911 agree with the known declination curve; and when the declination values determined from observations on earlier lava flows of known date were plotted, it was found that a curve was obtained which continued the known curve symmetrically backward, passing through zero about 1630, through 18° E. about 1440, and again through zero towards westerly declinations about 1240. The time intervals from zero to zero are nearly equal, and the amplitudes of the easterly and westerly declination are the same. The curve of dip shows irregularities which are attributed to the influence of adjacent lava masses.

ATMOSPHERIC IONISATION.—In 1910 and 1911, by observation of the ionisation of the atmosphere at different heights, Gockel came to the conclusion that the radiations due to the radioactive processes taking

place in the earth's crust and in the lower atmosphere were not capable of explaining the conductivity of the upper atmosphere, and suggested that penetrating γ -radiations entered the atmosphere from outside. Since then a large amount of work on the subject has been done, which is summarised and discussed by Dr. Walter Schulze in the *Naturwissenschaftliche Umschau* for July. He comes to the conclusion that the existence of such a hard γ -radiation has been established, and that it originates either in the upper atmosphere itself, or more likely in the neighbourhood of the Milky Way.

QUARTZ FILTERS.—The *Chemiker-Zeitung* for August 25, p. 716, gives an account of some experimental tests on quartz crucibles with filtering bottoms made by the Jena firm of Schott und Gen. The porous bottoms are made from the same material as the crucibles themselves, and in the case of those made from rock-crystal the analytical results were highly satisfactory, even when normal solutions of ammonia or caustic alkalis were used for washing the precipitates. The speed of filtration is rather slower than with the ordinary asbestos pads in Gooch crucibles. The analytical results obtained with the opaque crucibles were not quite so good, but the latter are suitable for filtering very hot liquids.

HIGH FREQUENCY VIBRATIONS IN PIEZOELECTRIC CRYSTALS.—A new method for showing the vibrations produced in piezoelectric crystals by an alternating electric field is described by Messrs. E. Giebe and A. Scheibe in the *Zeitschrift für Physik* of August 8. A suitably cut rod of quartz, the length of which was either 100 or 80 mm., the breadth 3 mm., and the thickness 1.5 mm., was in the simplest case placed between two electrodes connected to an oscillating valve which could be tuned to different frequencies. One of the electrodes, E_2 , was separated from the quartz rod by about 0.5 mm., and it was found that, when the bulb containing the electrodes was evacuated, a discharge took place in the space between E_2 and the quartz rod when the frequency had a certain very definite value, which corresponded to a longitudinal vibration of the rod with a node at the centre. The luminosity was greatest at the centre. W. G. Cady showed in 1922 that a crystal rod was set into longitudinal vibration in a suitable alternating field in virtue of the reciprocal piezoelectric effect, and in the present experiments these vibrations produce in the crystal alternating positive and negative surface charges which depend on the alternating compressions and rarefactions, and are therefore greatest at the node; these charges alter the electric field and facilitate the electric discharge. It is possible by means of a suitable system of electrodes to obtain a similar effect for an upper harmonic of the fundamental vibration of the rod, and photographs are given showing the appearance of the discharges for a number of upper harmonics up to the fifteenth.

THE PRODUCTION OF HELIUM IN GERMANY.—Since there are no natural gas sources from which helium can be obtained in Germany, experiments are being carried out at the Physikalisch-Technische Reichsanstalt in Berlin on the production of helium by other methods. An account is given in *Die Naturwissenschaften* (1925, p. 695) of the isolation of the gas by Dr. Walther Meissner by liquefaction from the helium-neon mixture, which is a by-product of the Linde Oxygen works. The Linde process is applied, liquid air and liquid hydrogen being used as refrigerators. It is claimed that the method is simpler than those used by Prof. Kamerlingh Onnes in Leyden and by Prof. McLennan in Canada. A second method described by Kurt Peters (*ibid.* p. 746) is by

heating monazite sand, containing 5 to 7 per cent of thorium, to 1000° C. One litre of helium was obtained thus from 1 kilogram of the sand. It is pointed out that the German thorium factories, which produce 60 tons of thorium nitrate annually from 500 tons of monazite sand, could recover between 250 and 500 cubic metres of helium.

NITROGEN FIXATION.—An interesting illustrated account of the synthetic ammonia processes of Casale and of Fauser is printed in *La Nature* of August 22. Both these processes are now in use on the manufacturing scale. The Casale process is more or less identical in principle with the well-known Haber process, but the details of working are different. Hydrogen is generated in the pure state by electrolysis of water; the nitrogen is obtained by mixing air and hydrogen in such proportions that on ignition all the atmospheric oxygen is removed as water, leaving nitrogen and hydrogen in the correct proportions for combination. The dried gas mixture is pumped through a heat recuperator and thence into the catalyst furnace. This consists of four concentric tubes. The electric heating element is placed in the centre tube; the next annular space is packed with catalyst (an active form of iron). The two outer annular spaces act as a heat exchanger. The gas mixture passes through the outer annular space (which is heated by hot gases from the catalyst chamber passing through the next space) and thence over the heating element in the centre tube. They pass from this to the next tube, containing the catalyst, and then into the third annular space, from which they are drawn off. This furnace economises heat. The exit gases pass once more through the heat recuperator and then to a refrigerator where liquid ammonia is condensed out. This economical process is now being worked at Terni and Nera Montoro (Italy), at Toulouse, in Belgium, Japan, France, Spain, Switzerland, and United States. In the Fauser process hydrogen is prepared electrolytically, mixed with nitrogen (see below) and compressed to 300 atm. During the compression a small quantity of water is added, which serves both as lubricant and to absorb the ammonia. The mixture is passed over the catalyst and then proceeds to the absorber. The aqueous ammonia solution thus obtained is distilled, the vapours being collected in a gasometer. The ammonia is then oxidised to nitric acid by mixing with air and passing over heated platinum. The excess nitrogen from the air, which proceeds from this apparatus, is used to mix with the hydrogen in the synthetic plant. The process is in use at Novara, Marengo, and other Italian towns.

MODERN LOCOMOTIVES.—The August issue of *La Science Moderne* has a well-illustrated article of 14 pages on the modern locomotive by M. Leftot, of the testing department of the Orleans Railway. The modern locomotive is the same in type as the one of 1845, and has now reached a stage in its development when increases of power or efficiency are only likely to be brought about by radical changes in construction or working. The present weight of European locomotives is about 12 tons, the steam pressure between 200 and 300 lb. on the square inch, and the power 2000 H.P. Oil fuel has been tried, but the increase of the price of oil has retarded progress in this direction. Powdered coal produced immediately before use in the furnace has been used successfully in America. Compounding and superheating are customary on some lines. The author considers that the future lies with the steam turbine and the heavy oil motor, and gives some details of European locomotives constructed on these lines.

Experimental Zoology in Poland.

WE have recently received several volumes of the Bulletin International de l'Académie Polonaise des Sciences et des Lettres covering the period June 1922-May 1924. The following notes based on communications in the Bulletins will serve to indicate some of the activities of workers in Poland in the field of experimental zoology during this period.

In "L'hérédité dans les cellules végétatives au cours de la régénération chez l'axolotl" (Bulletin, June 1922) Godlewski records his endeavours to discover whether somatic cells as distinct from genital cells preserve their inborn characters when transported to a new environment, or whether in such circumstances they "acquire" new characters. He transplanted a small piece of the skin of a black axolotl to a previously prepared spot on the base of the tail of an albino axolotl from which he had removed the skin. The new graft effected a satisfactory union with the neighbouring tissues and the animal was kept alive for five years. After the graft had united with the neighbouring skin, the tail was removed by a cut passing through the graft, and in about six months a new tail had been completely regenerated.

It is obvious that the grafted skin would necessarily take part in forming the new skin covering the regenerated tail, and the question was whether the new cells produced from the black skin would remain black or not. It was found that as the tail grew a black band of skin extended from the graft towards the tip of the tail, but that as time went on this band became narrower, and finally, after about two years, completely disappeared; but the area covered by the original graft maintained its black colour. Hence Godlewski concludes that the new cells derived by division from the black cells of the graft retain for a time their "inborn" black character, but that as time goes on their descendants slowly "acquire" the albino character of their environment and transmit this new character to their later descendants.

The original graft alters its position somewhat and moves slowly towards the base of the tail, but does not achieve more than a moderate change of position. This puzzling fact Godlewski explains by the assumption that in regeneration the skin grows more quickly than the other tissues, and so glides over them towards the tip of the tail.

Godlewski obtained a different result when he grafted a piece of skin from an albino axolotl on a wound in the base of the tail of a black axolotl. In this case the grafted piece of white skin soon assumed the colour of its black surroundings. This is explained by assuming that the skin chromatophores from the surrounding black skin migrate into the graft and change its colour.

Z. Kolodziejski has a paper on "Studies on the Metabolism of the Budding Hydra" in the Bulletin for October 16, 1923. In some cases of budding, as for example in Annelida, it has been shown that physiological differentiation is subsequent to morphological differentiation. Thus the reaction of the front part of the gut of an Annelid is acid whilst that of the remainder is basic, but the whole alimentary canal of the bud is basic in its reaction until its development is complete, and then alone physiological differentiation sets in. The primary object of the author was to discover whether similar differences in capacity existed between the mother Hydra and its immature buds.

The bud of Hydra is not formed as a simple eversion of the body-layers of the mother. It originates as a local thickening of the interstitial cells of the ectoderm, which penetrate between the neighbouring ectoderm

cells and, after having pierced the supporting lamella, between the endoderm cells also. These young cells gradually become transformed into ordinary ectoderm and endoderm cells, and the mass becomes hollowed out and forms a young bud.

When Hydra is fed on food coloured with Sudan red or on naturally coloured food such as green infusoria, the fate of the food can be followed. The author in this way confirms previous accounts to the effect that the food is first partially dissolved and converted into an emulsion with solid particles by the action of ferments secreted by special gland cells. Thus the contents of insect larvæ provided with hard chitinous coverings such as those of Chironomus or Corethra are dissolved out. The particles are afterwards ingested by amoeboid action on the part of the large endoderm cells. The use of colour indicators proves that the endoderm cells have a basic reaction. All the endoderm cells both of mother and bud are equally active, and the particles of the food emulsion penetrate even into the tentacles, especially into those of the bud, which have wider internal openings than those of the mother.

When a brown Hydra is fed on the green infusorian Euglena, the chlorophyll is ingested by the endoderm cells and the animal appears like a green Hydra; but the chlorophyll is finally completely digested and disappears. Hydra can be induced to ingest fat by mixing it with protein; the fat globules afterwards appear in the endoderm cells but are very slowly dissolved. Starch is at once rejected as indigestible material. The brown granules of the ordinary Hydra, which give to it its characteristic colour, are of an excretory nature. They have a crystalline character which is revealed when they are examined by polarised light. They are not influenced by alcohol, ether, or chloroform, but yield slowly to the action of 10 per cent solutions of caustic potash and soda, and of hydrochloric, nitric, and sulphuric acids. The author considers that they are probably allied to guanin. After solution the colour remains as an amorphous mass, and is to be looked upon as another substance which is being excreted along with the supposed guanin.

S. Skouron in "Le Rapport plasmo-nucléaire pendant la Spermatogenèse chez *Helix pomatia*" (Bulletin, May 1924) examines the question whether there might be an emission of nuclear substance into the spermatogonia of Helix. He preserved the ovo-testes in corrosive sublimate and acetic, and determined by comparison with living material that this preservation produced no change in the nucleo-plasmic relation.

The youngest spermatogonia had large vesicular nuclei with a very fine spireme of chromatin. As the cell grows this spireme thickens and becomes contracted into a closely woven tangle of chromatin at one side of the nucleus. This stage is of course that of "synapsis." Afterwards the tangle loosens, distinct chromosomes appear, and the nucleus and cell divide into two. The later generations of spermatogonia are distinguished by their larger size, and by the fact that even in the resting nucleus the chromatin can be seen as thickenings of the nuclear network. There is always a "yolk-nucleus" or "Nebenkern" in the protoplasm at the side of the nucleus. The period of growth is terminated by the formation of the spermatocytes of the first order, distinguished by their comparatively large size and by the arrangement of the chromatin material in tetrads. The spermatocytes, by the reducing or meiotic division, become spermatocytes of the second order; by another division following immediately on this, each

spermatocyte forms two spermatids. These are much smaller cells with nuclei filled with large and small granulations of chromatin. The spermatids by a series of well-known changes are converted into the spermatozoa.

The proportion of plasma to nucleus in young spermatogonia is about 2.3-1; but in spermatogonia in which synapsis has set in, it varies from 1-1 (equality) to 0.7-1. These figures indicate an enormous growth of nuclear matter which can actually exceed in bulk the remaining plasma. But if we follow the proportion between protoplasm and nucleus in subsequent generations of spermatogonia, we find that this in the first succeeding generations rises to 2.5-1 and in the later generations increases to 5.3-1. As the latest generations of spermatogonia are changed into spermatocytes of the first order, this proportion rises to 6.8-1. After the formation of the spermatids, and during the growth of these, the proportion rises to 19-1.

In the spermatogenesis of *Helix* there often occur polynuclear cells each of which gives rise to several spermatozoa. These cells result simply from nuclear division unaccompanied by cell division. If we compare the relation of protoplasm to nucleus in these cells we find that it runs through a series of changes parallel to those undergone by the plasmo-nuclear relation in normal spermatogonia. During the whole period of development of the sperm cells there is never any evidence of the emission of chromatinic substances from the nucleus into the protoplasm such as occurs in the egg.

Jean Prüffer contributes an interesting paper on "Observations and Experiments on the Phenomena of the Sexual Life of *Lymantria dispar*" (Bulletin, January 8, 1923). The pairing impulse becomes active as soon as the imago of the Gypsy-moth emerge from their cocoons, and since a large number of chrysalides are found on the trunk of the same tree and the males emerge first, the latest males to emerge fertilise the first females. But a great deal of pairing occurs during the subsequent lives of the insects; and to accomplish it the males fly long distances, their flights occurring only by day. The females, though inactive by day, fly about at night.

Experiments proved that the males were able to seek and find the females, when their eyes were covered with an opaque substance, when their wings were removed, when one entire antenna was removed, and when the distal portions of both antennæ were removed. When both antennæ, however, were entirely removed, the males were unable to find the females even when their eyes were uncovered. It is obvious, therefore, that the sense organs which serve to detect the female must be situated in the basal portion of the antenna, and we may remember that it was in this region that Mr. K. M. Smith, of the Imperial College of Science, now at the University of Manchester, discovered and described highly developed sensory pits in flies.

The attractiveness of the female for the male was not diminished by the removal of the "scales" from the female's wings, nor by the removal of its wings, nor by the amputation of the two antennæ; but it was diminished and rendered uncertain by the removal of the scales from the abdomen, and entirely destroyed by the amputation of the abdomen. On the other hand, the amputated but otherwise uninjured abdomens of females were as attractive as the uninjured insects. It is obvious, therefore, that the hedonic scent which emanates from females and attracts males is localised in the abdomen and especially in the scales covering the genital region.

It has been shown that in newly hatched pigeons

the liver and pancreas increase rapidly in weight, and that their rate of increase is out of all proportion to the increase of weight in the animal. Nevertheless in sections, no signs of either mitotic or of amitotic division of cells is to be seen. In the full-grown animals the liver and pancreas decrease in weight. In order to investigate this matter further, young pigeons were killed on the first, third, and fifth days after hatching and thereafter on every second day until full size was attained. The liver and pancreas were weighed in each bird thus examined and portions of these organs fixed and sectioned. ("Cell Growth and Body Growth Investigations in Pigeons," by L. Kaufmann. Bulletin, April 1924.)

It transpires that the cell volume increases most rapidly between the first and third day (about 50 per cent). Between the third and fifth day the rate of growth decreases, and on the ninth day the cells are actually smaller, a proof that cell division has taken place. The nucleus undergoes its greatest growth during the first two days, but in seven-day old pigeons it is only as large as nuclei in one-day old pigeons, and in still older pigeons it is even smaller, so that from the ninth day there may be said to be a permanent shift of the nucleo-plasmic relation in favour of the plasma. In one-day old pigeons the plasma exceeds the nucleus in volume 12.4 times, but in the full-grown bird the volume of the plasma is 66 times greater than the nucleus. After the seventh day, the number of karyokinetic figures diminishes and the increase in volume of cells is roughly proportionate to the increase in weight of the whole organ. As the liver is a storage organ, its weight increases with feeding and diminishes during fasting more than does the weight of the body as a whole. The decrease in weight of the liver in old birds is associated with a diminution in cell plasma.

In the growth of the pancreas, similar phenomena were observed, but the following differences are to be noted. The liver cell of the adult has five times the volume of the liver cell of the one-day old bird, but the pancreas cell of the adult is only twice the volume of the corresponding cell in the one-day old bird. The highest curve of increasing weight in the pancreas corresponds to the lowest curve of increase in cell-volume, whereas in the liver the lower curve of increase in liver weight corresponds to the higher curve of cell growth.

The author concludes that the nucleo-plasmic ratio has not, as had been previously supposed, a fixed point of equilibrium for each species, but that with each change in the general physical condition the nucleo-plasmic area may undergo alteration. Further, increase in volume and weight may be due to increase in amount of deutoplasmic substances and not of plasma.

Since Urodela are probably the most primitive land vertebrates now surviving, the mode of development of their blood-vessels, as indeed of their other organs, becomes a matter of interest and importance. This development had previously not been satisfactorily traced back to a sufficiently early stage of development; former authors relied mainly on sections, but Z. Grodinski ("Über die Entwicklung der Gefässe des Dotterdarmes bei Urodelen," Bulletin, February 11, 1924) has made successful injections of exceedingly young larvæ beginning with those only 4.5 mm. long.

These "larvæ" are really embryos with the tail and head merely indicated. In this youngest stage the main blood-vessels arise as metamerically arranged transverse branches from the aorta which unite with one another on either side to form a longitudinal vein at the level of the ventral edges of the myotomes,

which the author terms the *vena mesenterica*. From this vena mesenterica, further transverse vessels arise running half-way round the yolky gut and uniting on each side in its ventro-lateral region to form another longitudinal vessel, which are termed the *vena omphalo-mesenterica*. In older larvæ (5.5 mm in length) these two omphalo-mesenteric veins unite to form a single median *sub-intestinal* vein, which loses itself in the liver in front, and behind is continuous with the caudal vein. The *venæ mesentericæ* open into this sub-intestinal vein in front.

When the larva has attained a length of 7 mm. the yolk begins to disappear rapidly and the gut consequently to shrink in diameter. The *vena mesenterica* of each side moves in a dorsal direction, and so approaches its fellow. The two become connected

by transverse anastomoses and finally fuse into one. This single vein in the region of the duodenum describes a loop and fuses with the sub-intestinal vein. The transverse branches connecting it with the sub-intestinal vein become transformed into a network enveloping the intestine. Those branches which connected it with the aorta disappear. The hinder end of the sub-intestinal vein now disappears, and finally only a small anterior portion of it remains where it receives the mesenteric vein. The posterior cardinal veins begin as vessels draining the developing pronephros on each side. These gradually extend backwards until they reach and unite with the caudal vein and drain off its blood, and it is this new connexion which leads to the disappearance of the sub-intestinal vein.

E. W. M.

The Source of the Cold Air of the North "Polar Front."¹

By Prof. W. H. HOBBS, University of Michigan.

DENUDED of its liquid envelope, the figure of the earth may be compared to that of a tomato having a flat lump affixed at one side of the depression from which the stem has been removed. Not a close parallel—even a caricature—but I trust a true one, and successful caricatures are full of meaning. It is necessary to place the tomato in such position that the depression represents the deep basin of the Arctic Ocean, the bulging portion which is opposite will then represent the flat ice-dome of the Antarctic continent, and the artificial lump beside the depression the entirely similar though somewhat smaller ice-covered continent of Greenland. Both of these domes rise to elevations of nearly two miles above sea.

No adequate treatment of the atmospheric circulation is possible unless account be taken of this unsymmetrical figure of the earth; though, curiously enough, it has been the rather general custom to discuss the circulation of the atmosphere as though the areas surrounding the two ends of the earth's axis were characterised by exactly similar conditions. The theory of Ferrel, and the newer conception of Bjerknes which seems to have taken its place, alike ignore the contrast which exists between the two polar regions.

Bjerknes, in reviving an older view of von Helmholtz, has assumed that because of exceptionally high irradiation about both poles of the earth there must be formed about them caps of cold air with corresponding areas of high pressure; and that this cold air must pour out in all directions and meet the warmer air from the equatorial regions upon a surface of discontinuity—the "polar front."

Of the existence of a source of cold air within high latitudes, and the families of cyclones associated with it which the Bjerknes, father and son, have made known in a series of brilliant monographs, it is impossible to doubt. The individual characteristics of the cyclones composing a family within which youthful characteristics and notably turbulence are found curiously reversed, the crescendo of vigour which they display in sequence, and the abruptness with which the series comes to an end—these discoveries must be accounted as very important contributions to meteorology.

It is the field to which Bjerknes's keen research has not been directly extended, but within which the chief foundation of his theory has been laid, toward which I now direct attention. Is the north polar region one of high atmospheric pressure from which cold air is poured outwards? Fortunately the data

for a satisfactory answer are present, and the decision must be in the negative.

We may perhaps conveniently limit the north polar region by the parallel of 80° N., which will bring within it the entire Arctic Ocean for the sectors facing Europe and eastern North America, and will include upon its margins relatively small portions only of the land masses which in part bound that ocean. So far as explored, and with little doubt throughout, this entire area is deep sea covered with floating ice-cakes, which are continually drifting and which in no case rise more than a few tens of feet above the surface of the sea.

During the years 1894-96 the *Fram* drifted far into this region, and for the entire calendar year 1895, when the ship was nearest the Pole, it zigzagged along the 85th parallel of latitude. The mean daily atmospheric pressure for this year based upon complete data was 761 mm., with very slight seasonal or monthly range of pressure. Mohn, who discussed the meteorological data on the basis of the entire drift,² wrote: "The pressure at the North Pole seems to have its maximum—about 764 mm.—in April, and minimum—759 mm.—from June to September. This gives an annual range of only 5 mm." As I have divided the cruise, for the calendar year 1894 during which the *Fram* zigzagged between latitudes 79° and 84° N., the mean annual pressure was 758 mm.; and for the seven months of 1896, which were about equally divided between winter and summer, during which the vessel ranged in position from lat 85° to 81° N., the corresponding figure was also 758 mm.

These essentially normal figures obtained for the mean annual atmospheric pressure of the north polar region are, moreover, confirmed by the observations made by other explorers within the region or very close to its border, as the following figures will show:

Place	Latitude	Explorer	Mean Annual Pressure
Cape Flora . . .	79° 77'	d'Abuzzi	mm.
" . . .	"	Fiala	760
" . . .	"	Jackson	753
Rudolph Island . .	81° 13'	Nansen	756
Teplitz Bay . . .	81° 27'	Fiala	757
Moser Bay . . .	79° 57'	A. E. Nordenskiöld	754
Advent Bay . . .	79° 9'	Wegener and Robitzsch	757
Fort Conger . . .	81° 40'	Nares (1875-76)	756
" . . .	"	Greely (1881-82)	759
" . . .	"	" (1882-83)	758
" . . .	"	Peary (1909-10)	759

¹ Paper presented to Section E (Geography) of the British Association at Southampton on August 28.

² H. Mohn, The Norwegian North Polar Expedition, 1893-96, Scientific Results, edited by Fridtjof Nansen, vol. 6, London, 1905, Meteorology, p. 572.

There is here a quite monotonous uniformity, and the records for winter and summer months considered separately are similarly uniform, as the range in pressure is throughout very small and quite in harmony with the known characteristics of an expanse of frozen sea.

The one continuously high pressure area of large dimensions to be found within high—though not polar—latitudes of the northern hemisphere, is the continent of Greenland, with the geographical centre distant some nineteen degrees from the North Pole. Greenland is a flat dome of snow-covered ice rising nearly two miles above the sea and, thanks to Peary and a long line of distinguished Danish explorers, of which Lauge Koch is the latest, Greenland is far better known than is its sister ice-dome in the Antarctic. Summer and winter alike it is overlaid by a high pressure area, and the anticyclonic circulation is characterised by powerful pulsations, or *strophs*, which begin gradually, develop centrifugal surface winds in a mighty crescendo of vigour often culminating with hurricane intensity. This outward flow of cold air drops down off the ice-dome and comes to a sudden halt at the culmination of its intensity. With this abrupt termination are associated a sudden rise of temperature and all the other characteristics of falling winds—foehns. As a surface wind this air does not pass out beyond the coast of Greenland, and must in consequence rise in the passing cyclones of which the coast line is the common border with the anticyclone.³

The fixed anticyclone of Greenland and the corresponding one over the Antarctic must not be confused with migrating anticyclones, which they resemble only in the direction of rotation and vertical movement, and very little in their quantitative attributes. They are the great drainage shafts for the high level currents as well as reversing positions for the general atmospheric circulation—they are the wind poles of the earth.

Of the "polar front" Bjerknes says:⁴ "On the north side of this line all signs indicate air of polar origin; it has a low temperature for the latitude, shows great dryness, distinguishes itself by great visibility. . . ." Now these are not the characteristics of the air over the polar sea, where rain and fog are common, but just those of winds which drop down from a height, and such conditions are nowhere observed in such perfection as on the borders of Greenland. Moreover, the winds of the European sector of the north polar region are not outward toward Europe. They are extremely variable in direction, but winds of southerly component are somewhat more common than those of northerly component.

To bring out clearly the relationships of the strophic outpourings of cold air from the high continent of Greenland to the cyclone families of which J. Bjerknes has furnished so intimate a portrait, it will be necessary to state the salient characteristics of these interesting cyclones.

Each cyclone family is made up of sometimes two but generally four to six cyclones in succession, designated in order A, B, C, and D, with sometimes

E and even F, and these cyclones represent a crescendo of vigour. They usually pass eastward during a period of about six days and on paths which diverge from some point near to but west of the coast of north-western Europe. Cyclone A is weak and sluggish in its movement, travels slowly, and generally pursues a course over Norway to the Arctic. It seems to be in a dying condition, and this is interpreted to mean that it has travelled from some region far to the west of Europe. Cyclones B and C, starting from some point west of Europe but relatively near, swing to the right and pursue their way farther south so as to pass over Sweden and Finland. D cyclones either follow this route or steer still farther to the right over Denmark, southern Sweden, and the Baltic; whereas E cyclones, if they are formed, pass either along this latter route or still farther to the southward.⁵

Now with the exception of the first one or two members of a cyclone family, which Bjerknes and Solberg believe to have travelled a long distance, the remaining cyclones of the family are thought by them to have been generated relatively near to but west of north-western Europe.⁶ There is, I believe, confirmation of this near origin for all later members of the cyclone family in the fact that such families have not been recognisable in the United States,⁷ and there is much reason to believe that those cyclones which are passing Greenland at the times of outpouring of cold air (strophs) within the Greenland glacial anticyclone, are by it rejuvenated and have imparted to them a measure of vigour which is dependent upon the stage to which the stroph has evolved at the time. The crescendo of vigour, the sudden halt, and in a rough way the period covered, are all closely in correspondence between the stroph of the anticyclone and the cyclone family.

Enough has been said, it is believed, to bring out the intimate relationship which appears to exist between the cyclone families of western Europe and the glacial anticyclone of Greenland, also to show that the cyclones C to E of each family are probably rejuvenated as they pass the east coast of Greenland; and that the cold air supply of the "polar front," instead of coming from the north polar regions, is due to outpourings from the strophs of the Greenland anticyclone. If there is a surface of discontinuity between this cold air and the warmer air of equatorial origin, this so-called "polar front" should be known as the *Greenland front*.

The close correspondence in time of the arrival at the Greenland coast of foehn winds from the interior with the passage of strong cyclones along the coast, was long ago observed on the west coast by Rink⁸ and on the east coast by Holm⁹; and confirmation has been found in the work of later observers, notably Stade.¹⁰

To give warning of the coming of dangerous cyclones to the coast of Europe, Bjerknes has recommended that a meteorological station equipped with wireless be established on the southern point of Greenland. A better locality for such a station would be opposite the widest portion of the continent, but this station should be located upon the slopes of the ice-dome at an elevation of at least 3000 feet, since the outstreaming currents

override in large measure the lower strata of air. The tumult of the tempest above is often heard in the fjord as a dull roar, though the surface of the water is not stirred by a ripple.¹¹ The projected Danish Greenland Expedition of 1926-27, which is to be commanded by Dr. Lauge Koch, will for the first time afford an opportunity to put this suggestion to a practical test, for his base is to be located on Scoresby Sound. On the border of the Antarctic ice-dome, Sir Douglas Mawson, equipped with wireless, was able in 1911-14 to show that the outrushes of cold air preceded by about forty-eight hours the arrival of strong cyclonic disturbances at the Australian south coast.¹² Some such prevision for north-western Europe should be possible from a station on the Greenland dome, or on high land outside reached by the strong slope winds.

Transport Problems.

AT the Southampton meeting of the British Association, Section F (Economic Science and Statistics) joined with Section G (Engineering) for the discussion of transport problems. A two-days' joint meeting was held concurrently with the separate meetings of the respective sections.

On the first day the representatives of the engineers discussed the more technical aspects of the road problem. Col. H. T. Tudsbery, of the Ministry of Transport, read a paper on "The Economics of Highway Engineering," in which he dealt with traffic matters and the construction, maintenance and design of roads. Stressing the cost involved in traffic delays, he computed that one-third of a lorry's time in the London dock area is consumed by traffic delays.

Mr. Philip Johnson, speaking of the "Roadless Vehicle," indicated the great scope available to such vehicles in undeveloped countries where railways or roads would be too expensive to build. He suggested that in much less time than it has taken to develop road vehicles to the present stage, roadless vehicles will show a similar development. He believed that there can be little question about the demand for them, since that portion of the world which is well equipped with roads is an insignificant fraction of the areas where no efficient transport facilities exist at all.

The third paper, by Mr. W. Maughan, dealt with the classification of roads. He described some early road censuses of traffic that he had undertaken, and stressed the importance of accuracy in that work.

On the second day three papers were read by members of the Economic Section. Mr. Tetley Stephenson discussed the "Present Position of British Railways." Somewhat pessimistic in tone, he emphasised the effects of the competition of road transport. He alleged that in practice the road haulier had a subsidy, since part of the cost of road repair was borne by the local taxpayer. He advocated relief from such local taxation imposed on the railways. He referred also to the fact that the British trader demands a very high quality of service, expecting rapid delivery and no waiting for full loads—factors, of course, that tend to increase cost. The trader also demands and obtains a long period of free demurrage—an expensive form of warehousing to the railways. Emphasising the necessity of operating economies, Mr. Stephenson stated that, as the labour bill accounts for 65 per cent. of the expenses, economies must inevitably involve a material reduction in this item.

A paper on the "Economics of the Modern Port," by Mr. Alfred Schofield, outlined the development of the modern port. Two of the factors, he said, which

determine the economic importance of a port are the hinterland which it serves and the nature of the shipping that is cleared at it. A large port cannot, however, live on passenger traffic alone. Trade in Great Britain tends to concentrate in five or six leading ports, and the future lies with the large port.

The third paper was read by Mr. K. G. Fenelon, who took as his subject "The Development and Economic Significance of Road Transport." In the first part of his paper, which was mainly statistical, he illustrated and analysed the growth in the number of motor vehicles in Britain, from some 854,000 in May 1921 to some 1,420,000 in May 1925. In about the same period the increase in the U.S.A. was from some 9,200,000 to some 17½ million. The reasons for this great development are to be found in the economic advantages of road transport. Road transport is flexible, door-to-door services can be provided, and but a small capital outlay is required to purchase a vehicle. On the question of the economic significance of motor transport, Mr. Fenelon showed that it is opening up the country to an extent never before achieved, and that this has important bearings on social and industrial developments. Road transport is playing an important part in relation to agriculture and rural life, to housing and health, and to the further development of industrial technique.

University and Educational Intelligence.

NEWCASTLE.—Prof. H. V. A. Briscoe has been appointed director of the chemistry department of Armstrong College, Newcastle-upon-Tyne, in succession to Prof. W. N. Haworth, now professor of chemistry in the University of Birmingham. Prof. Briscoe has been for several years professor of inorganic and physical chemistry in Armstrong College. Dr. G. R. Clemon has been appointed professor of organic chemistry. He has recently been in charge of the research department of the British Dyestuffs Corporation at their laboratories at Manchester.

LAND-GRANT COLLEGE EDUCATION, 1910 to 1920, forms the subject of a series of studies which are being published by the United States Bureau of Education. The institutions known as Land-Grant Colleges were founded under the Morrill Act of 1862 and subsequent acts which provided for their endowment by grants of land by the Federal Government to the States, the primary object of the endowment being to ensure the teaching of "such branches of learning as are related to agriculture and the mechanic arts, in . . . order to promote the liberal and practical education of the industrial classes in the several pursuits and professions in life." They include 26 State universities, 17 institutions for coloured persons, and 26 other land-grant colleges. They are educating approximately one-third of all college or university students in the United States and three-fourths of all those trained at publicly controlled colleges and universities. Their total enrolments during the ten years 1910-1920 increased by 78 per cent.: the number of their women students doubled during the same period. It is obvious that they must have already exerted important influences on national development, and the importance of their functions ever tends to increase as the necessity for husbanding the natural resources of the country becomes more urgent. At the present rate of increase of the population, the United States will within about twenty years become a food-importing nation unless extraordinary efforts are made to increase production upon the present acreage.

Early Science at Oxford.

October 6, 1685. The Minutes of July 28th, 1685, being first read, the Secretary in ye name of Dr. Peirce of Bath presented ye Society with ye *shell* found by ye Doctor in ye kidney of a woman, and described in the *Philosophical Transactions*, No. 171, which very curious present was ordered to be repositied in the Musæum Ashmoleanum.

A letter from Dr. Middleton dated August 8, 1685 was read, it brought us a letter from Dr. Garden to Dr. Middleton concerning two monstrous Children lately born at Aberdeen; concerning the Sucker or Proboscis of ye Bee, and the Instruments, by which they break ye globulets, (or little bags of liquors) taken from the flowers, and prepare their wax: and also concerning ye circulation of ye blood, easily seen in ye *Lacerta Aquatica* by reason of its transparence.

A letter from Mr. Ja: Aston to Dr. Bathurst, dated Whitelackenden Oct: 1 1677, was communicated us from the Doctor. It gave an account of three Persons (one Man and two Women) in ye house of Mr. Speke of Whitelackenden taken with fitts, which came and went off in all and every one of them, though in distant places, at ye same time, and with the same symptomes; insomuch that if one laught, sung, curst, or ye like, the rest did so also.

Mr. President presented a booke, ye author Richard Norris, it treated of his manner of finding ye true sum of ye infinite of an arch, by an infinite series.

Proposals for printing Mr. Ray's History of Plants, together with a pattern of it, were presented.

October 7, 1684. Mr. Anderton, having formerly been admitted, acquainted ye Society, that a *spout* of rain fell between Farnborough, and Brittleton, in Barkshire, ye 3rd of May last; that ye fall of ye water was so violent, as to beat its way into a house on the top of a hill.

He says farther, that a woman near him in ye country, did, at 60 years of age, give suck to a little child; tho she herself had no child, nor given suck, for many years before.

Dr. Plot communicated an account of ye weather here at Oxon; in September last; He presented us with some of ye East Indian Bange, which is ye leaf of a tree taken commonly by ye inhabitants at their feasts; it is said to intoxicate, and put every man in his particular humor.

He also communicated an abstract of a letter, sent him by Mr. Todd, dated September ye 7th, from Rose Castle in Cumberland, concerning a salt spring, and another (Minerall) spring near Durham; as also concerning some Roman Urns which he promises to send us. Mr. Todd says in this letter, that as he traveld over Stane-Moor in Yorkshire, he observ'd ye River Greatah (which is about half as big as the Charwell) run underground for about a mile, so that he, and his company, past over it drye foot. The passage under ground is but narrow; so that in winter, when the streams are high, it keeps ye channell above ground.

October 13, 1685. A discourse entituled *Logica rerum* composed by Mr. Foley, Member of ye Dublin Society, and by him dedicated to ye Royall Society, was presented and read, and ye thanks of this Society ordered for it.

The Figures of some antiquities cheifly Roman, communicated by a Member of ye Royal Society were communicated.

A farther account of ye Aqueduct about Versaille was read; as also was a letter of Dr. Lister's to Mr. Ray, concerning some addenda to the *Ornithology*.

ERRATUM.—In this column of September 12, p. 415, line 12 from bottom, for *erythmiformis* read *crythmiformis*.

Societies and Academies.

PARIS.

Academy of Sciences, August 10.—The president announced the death of Hugo Hildebrand Hildebrandsson, correspondent for the section of geography and navigation.—André Blondel: The determination of the coefficient of hysteresis by means of apparatus with a rotating magnet.—Amé Pictet, Werner Scherrer, and Louis Helfer: The presence of argon in living cells. The presence of argon in yeast and in sheep's brain has been proved: further experiments are in progress to determine the origin of this gas.—C. Gutton and E. Pierret: The perturbations at the extremities of a line which is the seat of stationary electromagnetic waves. From a study of the harmonics the perturbation at the extremities of a line can be determined, and a curve or a table constructed giving the value of the perturbation for different wavelengths.—A. Grumbach and S. Schlivitch: The variation of the surface tension of liquids under the influence of radiation. The ordinary method based on the rise of a liquid in a capillary tube is not sufficiently sensitive to show the effect of radiation. A new method is based on the fact that if a drop of liquid is introduced into a horizontal capillary tube, and the surface tension of one meniscus is altered, the drop will move in the direction where the surface tension is greatest. In the experiments described one meniscus was exposed to the light of a mercury lamp; water, alcohol, and xylene were not displaced, but motion was observed with several liquids, including ordinary petroleum, aqueous or alcoholic solutions of fluorescein.—H. André: Conductibility by metallic colloids and its electro-technical applications.—W. Kopaczewski: Turgoelectricity.—J. Bougault: An example of ether-oxide ketone hydrate. The benzylphenylethylsuccinic acids.—Louis Glangeaud: The existence of the Aptian in the coast region of the province of Algiers and on its tectonic signification.—V. Agafonoff and Mlle. Malichef: The brick earth and ergeron of the plateau of Villejuif.—Mlle. Aimée Camus: *Hitchcockella*, a new genus of Madagascan bamboo.—Charles Kayser, Mlle. Eliane Le Breton, and Georges Schaeffer: Magnitude of the respiration of the tissues and active mass in the course of the development of organisms. The elementary respiration of homologous tissues of different individuals of the same species is greater the younger the organisms.—J. G. Szuman: The structure of the membrane separating the white and the yolk of the egg. P. Petit: The liquefaction of starch paste. G. Guittenne: The transformation of sulphur into sulphate by microbial association. The conversion of sulphur into sulphates is the work of two distinct races of organisms: one converts the sulphur into thio-sulphate, the other thiosulphate into sulphate.

August 17.—H. Deslandres: Complementary researches on the structure and distribution of band spectra.—Mlle. Sylvie Creanga: New properties of curves of constant normal curvature; their rôle in the representation of surfaces on parallel surfaces. Applications.—Ragnar Frisch: The semi-invariants of Thiele.—André Bloch: The non-uniformisability by meromorph functions of the most general algebraic varieties. N. Lusin: The problem of Emile Borel and the method of resolvants.—A. Dauvillier: Researches on the Crookes tube.—Y. Rocard: The diffusion of light and ratio of the absolute retardations in Kerr's phenomenon.—R. Fosse and A. Hieulle: The identification of glyoxylic acid by the action of hydrazine and xanthidrol, with

production of the dixanthylhydrazone of glyoxylic acid. The new substance is a definite crystallised compound, $[O(C_6H_5)_2CH]_2 = N-N=CHCO_2H$, and serves to detect 1.0 mgr. to 0.1 mgr. of glyoxylic acid in dilutions of 1 in 100,000.—William Herbert Hobbs: The asymmetry of the atmospheric circulation.—E. Rothé, J. Lacoste, and Mme. A. Hée. Earthquakes in France in 1924. A description of 24 earthquakes, mostly in the neighbourhood of the Pyrenees.

SYDNEY

Linnean Society of New South Wales, July 29.—H. J. Carter: Revision of the Australian species of *Chrysobothris* (Buprestidae), together with notes and descriptions of new species of Coleoptera. Nineteen species are described as new, including five Buprestidae, two Lucanidae, ten Tenebrionidae, and two Cistelidae. Keys are given for identification of species of Nyctozoisus and Seirotrana.—E. Cheel: Two new species of Callistemon, with notes on certain other species. One of the new species is nearest to *C. lanceolatus* and has been obtained from a number of localities in New South Wales and also in Gippsland; the type is from Nattai River. The other is from North Queensland and shows some resemblance to *C. linearifolius* and *C. rigidus*, but is distinguished by the less prominently veined leaves, paler filaments, and differently shaped fruits.—G. H. Cunningham: Gasteromycetes of Australasia. ii. A revision of the genus *Tulostoma*. The characters of generic and specific value are described; three species and one variety are described as new.

VIENNA.

Academy of Sciences, July 9.—J. Pollak and E. Gebauer-Fulnegg. On the action of chlorosulphonic acid on phenols.—E. Riess. On derivatives of the three cresols and of phenol. Disulpho-chlorides, sulphonylides, and neutral sulphuric ester are formed.—O. Tomaschek. On Exner's polarimeter and a way of applying this instrument.—F. E. Suess. Report on a geological excursion to Hauzenberg in the Bavarian forest: a contribution to the tectonic of granite.—E. Muller. Mid-point surfaces and a relative theory of surfaces.—K. Fritsch. Contributions to our knowledge of Gesneriaceae, the species of the genus *Napeanthus*.—O. Dischendorfer. Researches in the domain of vegetable chemistry. On the amyrin of elemi resin.—E. A. W. Schmidt. Communication of the Radium Institute, No. 178. Action of α -rays on aluminium. Radium C and polonium were used as sources of α -rays and the effect on H-particles explored.—M. Blau. Radium Institute, No. 179. On the photographic action of H-rays from paraffin.—G. Kirsch and H. Pettersson. Radium Institute, No. 180. On the reflection of α -particles at atomic nuclei. Reporting on experimental results of the retrograde method, it seems that for internal collisions between α -particles and atomic nuclei the energy and impulse law is not valid if only the α -particle and the nucleus are considered. Atom shattering with surrender of protons seems an attainable process for all elements by bombardment with α -rays. Various money grants are reported, including those to A. Ginzberger for publications on the change of species on islands, to F. Lieben for researches on the relations between the kreatin-kreatinin transformation and the sugar transformation, and to R. E. Mark for researches on the action of insulin on the linkage of sugar and phosphoric acid in the animal organism.

Diary of Societies.

SATURDAY, OCTOBER 3.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (Joint Meeting of the North-Western and Yorkshire Districts) (at Todmorden), at 2.30 — R. H. Matlock, R. Bruce, and others. Discussion on Regional Town Planning.

SMOKE ABATEMENT LEAGUE OF GREAT BRITAIN (at Buxton) — Conference on Smoke Abatement.

SUNDAY, OCTOBER 4

SMOKE ABATEMENT LEAGUE OF GREAT BRITAIN (at Buxton) — Conference on Smoke Abatement.

MONDAY, OCTOBER 5

SOCIETY OF ENGINEERS (at Geological Society), at 5.30. — Major V. A. M. Robertson. Bridges their Renewal in England and France during the Great War.

JUNIOR INSTITUTION OF ENGINEERS (North-Western Section) (at 16 St. Mary's Parsonage, Manchester), at 7.30. — J. D. Porteous. Responsibility.

SMOKE ABATEMENT LEAGUE OF GREAT BRITAIN (at Buxton) — Conference on Smoke Abatement.

TUESDAY, OCTOBER 6

ROYAL SOCIETY OF MEDICINE (Orthopaedic Section), at 5.30. — A. S. Blundell Bankart. The Physiology of Muscular Action (Presidential Address).

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at Caxton Hall, Westminster), at 7. — E. Ower. Practical Measurement of Air Flow.

INSTITUTE OF METALS (Birmingham Local Section) (at Chamber of Commerce), at 7. — Dr F. Johnson. Some Phases of Life in India.

ROYAL PHOTOGRAPHIC SOCIETY, at 7. — J. D. Johnston. In Search of the Picturesque (Lecture).

INSTITUTE OF METALS (North-East Coast Local Section) (at Armstrong College, Newcastle-on-Tyne), at 7.30. — H. J. Young. Chairman's Address.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Automobile Club), at 8. — K. Thomas. The Automobile Engineer (Presidential Address).

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15. — Dr G. Rohmer. Hungarian Calendar Customs.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (Glasgow) LIVERPOOL PSYCHOLOGICAL SOCIETY (at Liverpool University). — G. O. Field. Inaugural Presidential Address.

WEDNESDAY, OCTOBER 7

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8. — Investigations into the Analytical Chemistry of Tantalum, Niobium, and their Mineral Associates. — Dr R. Powell and Dr. W. R. Schoeller. III — A New Method for the Separation of Tantalum from Niobium; IV — The Detection and Determination of Tantalum in Niobium Compounds. — Dr. H. B. Darnell. The Determination of Sulphates in Gun cotton. — C. O. Harvey. The Reduction of Chloric Acid and Chloric Acid by Ferrous Sulphate.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

THURSDAY, OCTOBER 8

INSTITUTE OF METALS (London Local Section) (at Institute of Marine Engineers, 85 St. The Minories), at 7.30. — Dr J. L. Haughton. Chairman's Address.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at 8 St. Martin's Place, W.C.2), at 8. — Dr H. H. Morgan. The Need for Research in the Oil and Colour Industry.

FRIDAY, OCTOBER 9

JUNIOR INSTITUTION OF ENGINEERS (Informal Meeting), at 7.30. — Technical Questions and Discussions.

INSTITUTE OF METALS (Sheffield Local Section) (at Sheffield University), at 7.30. — F. Mason. Some Notes upon the Value of the Institute of Metals to the Local Industries (Chairman's Address).

SOCIETY OF CHEMICAL INDUSTRY (Chemical Engineering Group) (at Royal Society of Arts), at 8. — Dr W. L. Gibbs. Aerosols in Industry.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30. — G. Glegg, G. H. Pooley, H. Lee, and — Goulden. Discussion on Penetrating Injuries of the Eye.

DIESEL ENGINE USERS' ASSOCIATION (at Caxton Hall, Westminster) — E. M. Bailey. The Scottish Shale Oil Industry.

PUBLIC LECTURES.

WEDNESDAY, OCTOBER 7

UNIVERSITY COLLEGE, at 5.30. — Prof. F. Weigart. The Photochemistry of Vision. — At 7. — A. H. Barker. The Heating Equipment of a Large Hospital.

THURSDAY, OCTOBER 8

UNIVERSITY COLLEGE, at 2.30. — Sir Flinders Petrie. The Making of Egypt. — At 5.15. — Dr. T. G. Pinches. Recent Discoveries in Babylonia. (Succeeding Lectures on October 15 and 22.)

KING'S COLLEGE, at 5. — Dr. O. Da Fano. The Histology of Nerve Tissues and Paths of Conduction in the Central Nervous System. (Succeeding Lectures on October 15, 22, 29; November 5, 12, 19, 26; and December 3 and 10.) — At 5.30. — S. Smith. The Seals of Western Asia.

FRIDAY, OCTOBER 9

BEDFORD COLLEGE FOR WOMEN, at 5.15. — Miss Hosgood. Caribbean Countries some special Geographical Problems.

SATURDAY, OCTOBER 10.

HORNIMAN MUSEUM (Forest Hill), at 3.30. — Miss M. A. Murray. The Earliest Egyptians and their Remains.

SATURDAY, OCTOBER 10, 1925.

Physiology and Athletics.

PROF. HILL'S address on "The Physiological Basis of Athletic Records," an abridgment of which appears elsewhere in this issue, affords another instance of the value of laboratory work and its application to practical problems. The investigations of the functions of the isolated frog's muscle which were almost notorious for their supposed uselessness, have laid the foundation of the later work on muscular exercises. Prof. Hill does not claim that physiology can teach us how to win races, or, what is more important to certain sections of the public, "how to spot winners." The physiologist can aid, however, in the selection of men and women who are likely to become successful in the field of athletics.

The measurement of the gaseous exchanges of the body have been used for some time as a means of investigating certain functions of the body. In the hands of workers such as Haldane, Douglas and Krogh, among others, these methods have yielded results which have led to an understanding of the functions of the circulatory and respiratory systems. Benedict and Cathcart, by direct and indirect calorimetry, showed how the metabolism of the body and the physiological cost of work might be studied. Prof. Hill, by measuring (a) the maximum oxygen intake (income) and (b) the maximum oxygen debt, has extended the scope of these investigations. The measurements afford a means of investigating not only the metabolic changes during exercise, but also of studying the recovery process in the tissues after exercise is over.

It is clear that the measurement of the oxygen used will enable us to estimate the physiological cost of work, but movement to be physiologically efficient must be carried out in a skilful manner. The athlete who is able to go into debt heavily for oxygen is not necessarily the most skilful. The degree of skill which is shown will depend on factors such as posture, co-ordination of muscles, and the integrative action of the nervous system. Even the most simple movements of the body will on analysis be found to be exceedingly complex, many factors being harmonised to bring about the unity of motion. The work of Marey and the Webers demonstrated, many years ago, that the mere act of walking involved not only movements of flexion and extension of the lower limbs, but also accompanying movements of the shoulders, arms, head and hips. At each step, oscillations of the hips, shoulders and head occur. The leg that is moving forward is accompanied by a forward movement of the hips and a backward movement of the shoulders, that is, a slight twist of the trunk around a vertical axis. This torsion may be so exaggerated as to become very

apparent, but it is manifest to a slight extent even in normal walking, especially in women with a large pelvis. The torsion of the trunk and active oscillations of the upper limbs which balance the body increase on rapid walking. These accessory movements, unless reduced to a minimum, will lessen the efficiency of the movement and increase the physiological cost.

The muscular system which controls voluntary movement may be divided into three parts: (1) the prime movers, (2) the antagonists, and (3) the synergic group of muscles. Flexion of a limb is brought about by the contraction of one set of muscles, the flexors, and relaxation of the opposing set or extensor muscles, the two groups working in harmony. This dual action is essential and is found in every voluntary movement. To allow the third group, the synergic muscles, to function in a co-ordinated manner with the prime movers and antagonists, the limb or body must adopt the correct position. The action of the muscles, as pointed out by Magnus, depends on the posture. Bedale and Cathcart have recently investigated the physiological cost of work, by indirect calorimetry, in different types of weight-carrying, and their results show that the cost of work varies with the same load according to the posture adopted.

The body controls the movements of muscles and the posture of the part by the action of the nervous system. The regulating mechanism involved has been termed by Sherrington "the proprioceptive system," and includes nerve fibres from the muscles, tendons and joints, the internal part of the ear, and the external muscles of the eye connected through the various regions of the brain. In maintaining balance and posture each organ plays a definite part, regulating position, judgment of distance and the co-ordination of movement. The interaction and co-ordinated mechanism of these systems can be demonstrated by any skilled act, as, for example, movements of the expert skater in cutting a figure on the ice. It is impossible at the present time to express these various factors in measurable terms, but the investigations of the oxygen consumption correlated with the speed of movement gives a basis for discussion. It must be clear that a first-class athlete who is capable of breaking records does possess a high degree of skill in his movements. A man who is capable of establishing a large oxygen debt may become a record-breaker if he can be taught how to use his limbs to the best advantage. The elimination of unnecessary movements is receiving attention in the fields of athletics and industry. Slow motion photography and motion study are means by which the movements may be studied and faults corrected.

There still remains a factor of which we have little

knowledge, namely, the determination to win. How often is form upset on the racing track through a man losing his will to win at the psychological moment. This faculty, vague and indefinite as it may be, undoubtedly plays an important part in athletic life.

The comparisons drawn between men and women will be hotly contested, and Prof. Hill is a brave man to express the female performer as a fraction of a man. Certain anatomical differences in structure of men and women are known and probably militate against the female athlete. The flat female pelvis allows greater torsion of the trunk on exercise, and accessory movements of this nature will interfere with speed of action. Again, it is not clear that women up to the present have given as much time and attention to sport as men, and improvement is likely to be made by training and physical culture. Prof. Hill has arranged to carry out further work on this subject, and the results will be awaited with interest.

Fossil Insects of the Carboniferous Period.

A Monograph of the Fossil Insects of the British Coal Measures. By Dr. Herbert Bolton. Part 1. Pp. 80 + 4 plates. Part 2. Pp. viii + 81-156 + plates 5-10. (London: Palaeontographical Society, 1921-1922.)

PALAEONTOLOGISTS are now aware that, at the epoch when the coal beds of the Carboniferous Period were deposited, the arthropods were the first of all living creatures to gain the conquest of the air—these insects bore sway in that silent domain which as yet the birds did not dispute with them. This most ancient world of insects has been revealed by the progress of study as of so special a character that it cannot be brought within the narrow limits of the zoological classifications of the present day.

British palaeontologists possessed the honourable record, with regard to fossil insects, of having first discovered, early in the last century (1833), an impression of an insect in these carboniferous strata (*Lithosialis brongniarti* Mantell, 1854). They have now added to their list of successes a record which is still more glorious because it is due, not to chance, but to the sustained effort of one of their number—to-day the insect fauna of the British Coal Measures must be regarded as the best known of all those brought to light from all the Carboniferous basins of the world, thanks to the scrupulous and patient work which Dr. Herbert Bolton, director of the Bristol Museum, has carried out during close on twenty years.

The following figures will speak for themselves: in 1908, when Dr. Bolton began his investigations, only

thirteen species of fossil insects were known in the Coal Measures of Great Britain; Dr Bolton's researches have increased their number at the present day to almost sixty different species, contained in the five principal groups of these insects.

Dr Bolton has lately collected together the result of his studies in the remarkable monograph before us. This work does the greatest honour to British science. It is accompanied by a perfect set of figures consisting first of an actual reproduction, somewhat enlarged, of each specimen, due to the photographic skill of Mr. W. J. Tutcher, and giving a good idea of the exact nature of the impression, and secondly, of an outline drawing in which the author indicates the manner in which he has read the structure; thus the actual record is well separated from the interpretation. This is accompanied by a very precise description in the text. Dr. Bolton's monograph is thus of very great documentary value, and a model to all palæontologists for their descriptions. We can well imagine what an amount of effort and of patient criticism the author must have needed in order to present this memoir to the world of science. The difficulties must have been very great: it must be remembered that very small portions of the body of these creatures have been found, often only a tiny fragment, and these have been subjected to great pressure changes. When to this is added that in structure and relationship they differ widely from living forms, we cannot repress legitimate wonder that it has been possible, as with a magic wand, to bring to life, from a few fragments of stone bearing obscure impressions, so varied a swarm of unknown insects.

The greater part of this winged company revealed to us by Dr. Bolton's memoir is placed in the order Palæodictyoptera—he groups together the most curious of these insects, because they are the simplest, probably the oldest, and because they have no equivalents in Nature to-day, not having survived the Palæozoic era. Dr. Bolton describes nineteen species of them. These creatures appear to have flown, in large numbers and great variety, above the coal-swamps of Great Britain. They are provided with three pairs of wings possessing a very simple nervation, and with three pairs of legs, one pair of wings and legs to each thoracic segment. The legs are all alike; the first pair of wings (on the pronotum) is very much reduced, the hinder pairs only being functional; no specialisation of the organs of the mouth. The development is direct, without metamorphoses. In short, it appears as if these ancient Palæodictyoptera had almost exactly realised the *protentomon* formerly dreamed of by entomologists as the ancestral synthetic type of the Hexapods. Their size is variable and may reach a span of wing of about

30 cm. (*Hypermegethes northumbriæ*, Bolton) and even 70 cm. (*Archæoptilus ingens*, Scudder).

Besides these insects, also flying over the swamps and equally good sailers, were rarer forms which appeared later, more highly specialised and more similar to the insects of to-day: the dragon-flies. *Boltonites radstockiensis*, Bolton, found in the Upper Coal Measures of Somersetshire, is one of these curious Protodonata of large size (span of wing 40 cm.).

Following upon the Palæodictyoptera, the author describes a remarkable series of insects which Dr. A. Handlirsch, the Viennese entomologist, has placed in the two orders Protorthoptera and Protoblattoidea. As the names indicate, these insects are "generalised" types, very near to the living Orthoptera. Dr. Bolton describes eight species of Protorthoptera from the British Coal Measures.

Finally, an important section of these fossil insects (nearly twenty species) is formed by the cockroaches which, in the Coal Measure forests, under vegetable debris, lived in such large numbers and with so many varieties that Dr. Handlirsch has proposed to form a special order (Blattoidea) intended to contain them. S. H. Scudder was right in calling the Carboniferous Period "the era of cockroaches." Dr. Bolton has recognised that the English types had the closest relationship with those which we have described in the Coal Measure basin in the north of France. These innumerable cockroaches, the most minute details of whose organisation are known, are, except for a few primitive characteristics, constructed exactly after the same type as their rarer descendants of to-day. The latter, since the Carboniferous Period, have shown themselves proof against all evolution. They are *permanent* organic types, even more suggestive than the Lingula, often quoted on this account, for this is a case of animals which are very sensitive to change of surroundings, and very easily linked up with them.

Thus palæontology rehabilitates the cockroaches. They are far from meriting our scorn, for they are of aristocratic descent and the most conservative of all creatures. Is it in memory of the "Paradise Lost" of the Coal Measure forest where they reigned supreme, that they have become with most people the emblem, the *bête noire*, of their melancholy?

No insect in all the Coal Measure fauna is found undergoing complete metamorphoses, passing through the stages of caterpillar and of chrysalis before reaching the adult winged form. Dr. Bolton figures the larvæ of the Palæodictyoptera and of the cockroaches found in the English basins, which differ from the adult forms only by the lesser development of the wings, not in shape. The metamorphic insects (Holometabola) did not appear until the beginning of the Mesozoic Period,

at the same time that the seasonable alternations of heat and cold were produced. Doubtless there is a relationship of cause and effect. At any rate, the definition of a butterfly made by a French poet does not, according to the witty remark of Prof. Ch. Barrois, apply to these Coal Measure insects which lived before the seasons and the flowers existed: "Naître avec le printemps, mourir avec les roses." These insects, made known to us by Dr. Bolton, were born and died before the world had known the first spring-time and the first rose.

The greater number of the coal basins of Great Britain, and almost all the levels of the Coal Measures, but principally the Upper (Middle and Upper Coal Measures), have yielded fossil insects. From the point of view of their stratigraphical distribution, Dr. Bolton has established facts similar to those which have been recognised in France, namely: (1) In the Lower Coal Measures the Palæodictyoptera predominate, and cockroaches are rare; (2) in the Middle Coal Measures simple Blattoidea are found such as the Aphthoroblattina, and Protoblattoidea such as Coselia; (3) finally, at the base of the Upper Coal Measures flourish the genera of Blattoids, Archymylacris, Phylomylacris, Soomylacris, etc. . . ., as in France, in the Bruay beds. Thus the Coal Measure insects, which have evolved rapidly, are excellent fossils characteristic of the successive horizons.

In his introduction, Dr. Bolton touches upon a certain number of theoretical questions, such as that of the origin (aquatic or terrestrial?) of insects, the origin of their wings (which appear merely as an exaggeration of the pleural expansions which all Palæozoic arthropods bear on their segments). But he does not linger over them, because he rightly prefers to produce a work of actual observation, and he examines in detail the interesting question of the faunal association of the Coal Measure insects only because he has found in the beds a whole series of instructive facts. The frequent association of fossil insects with the Myriapoda and the Arachnidæ in the ironstones reminds him of the colonies of spiders, millepedes, and cockroaches living under the bark of trees which he has observed in the bush country of Australia. Even under a tropical sun the nightly dew preserves during the day, in the low parts of the jungle, conditions of humidity favourable to the life of arthropods, which Dr. Bolton compares with those which must have prevailed at the Coal Measure Period.

Such are a few of the reflections suggested by the reading of this memoir. When one reflects that, among the seventy specimens of insects dug up from the coal basins of Great Britain, there are almost sixty different species, one is struck by the great diversity of this

vanished world. Almost every impression which is discovered reveals an unknown organic type, so that the number of forms which we do not yet know must be immense. Therefore Dr. Bolton encourages us to seek for them: "The fossil insects already found in the British Coal Measures form probably but a small fraction of those which remain to be discovered, when attention is more fully directed to them" (p. 3).

In thus concluding a work of such great value, the fruit of so much conscientious labour, Dr. Bolton could not more modestly or more wisely apply the precept, "The man who has finished has only just begun." We hope for the sake of palæontological science that Dr. Bolton's wish may be realised by himself.

Modern Meteorology.

- (1) *Dynamische Meteorologie*. Von Prof. Felix M. Exner. Zweite, stark erweiterte Auflage. Pp. viii + 421. (Wien: Julius Springer, 1925.) 24 gold marks.
- (2) *Les méthodes de prévision du temps*. Par J. Rouch. (Nouvelle Collection scientifique.) Pp. 280. (Paris: Félix Alcan, 1924.) 10 francs.
- (3) *Wellen im Luftmeer: neuere Untersuchungen über Gesetzmässigkeiten im Gange und in der Verteilung des Luftdruckes*. Von L. Weickmann. Erste Mitteilung: Symmetriepunkte des Luftdruckganges der Luftdruck als zusammengesetzte Schwingung. Pp. 46 + 6 Tafeln. (Leipzig: S. Hirzel, 1924.) n.p.

(1) **P**ROF. FELIX M. EXNER is known to be the author of some sixty original papers, joint author of a standard work on "Meteorologische Optik," joint editor of the *Meteorologische Zeitschrift*, and Director of the Austrian Zentral Anstalt für Meteorologie und Geodynamik. His "Dynamische Meteorologie" is regarded as important by meteorologists, and will probably also interest those who teach dynamics, because it is largely written in their style; the "soluble" problems of atmospheric dynamics being set out in neat mathematical language.

The early chapters expound fundamentals concerning the distribution of gravity, the thermodynamics of moist air, the dynamics of a fluid on a rotating sphere, and the statics of an atmospheric column. So far the topics are common to many books. Much of what follows is original; indeed, we know of no other book that overlaps to any considerable extent.

The best way of classifying the enormous heap of meteorological facts and theories is a puzzling problem of which Exner's solution is to head chapters thus: iv. Vertical Temperature Distribution in Equilibrium, v. Kinematics, vi. General Dynamics of Air Currents,

vii. Energy of Air Currents, viii. Steady Motion in the Atmosphere, ix. General Circulation of the Atmosphere, x. Dynamics of Cyclonal Motion, xi. Non-periodic Changes at one Place, xii. Non-periodic Changes on the Map, xiii. Periodic Changes in the Atmosphere. Many ordinary topics run on from chapter to chapter, for example, the modern work on cyclones will be found in Chapters xi. and xii. as much as in x.

Some of Exner's prettiest results are obtained on the hypothesis that the air moves adiabatically, without friction, at a speed which, in view of the earth's rotation, just balances the pressure gradient. Meanwhile every column is supposed to be in vertical equilibrium. He thus (§ 76) derives the remarkable equation

$$\frac{\partial P}{\partial z} \cdot \frac{\partial^2 P}{\partial \sigma \partial t} = g \left[\frac{\partial P}{\partial y} \cdot \frac{\partial^2 P}{\partial x \partial z} - \frac{\partial P}{\partial x} \cdot \frac{\partial^2 P}{\partial y \partial z} \right],$$

in which x, y, z, t are the co-ordinates, z pointing vertically, g is the acceleration of gravity, l is z (earth's angular speed) $\times$ (sine of latitude), and P is the 0.288th power of the pressure. From this he deduces (on p. 299) a rule that may be stated thus: "If the isobars turn with increasing height in the direction of the sun's apparent daily motion, then, in the region of their turning, the potential temperature is rising; and vice versa." Next this rule is applied (on p. 350) to explain why it is that a shallow unsymmetrical cyclone usually travels eastwards. Again (p. 381) the same ideas enabled Prof. Exner to forecast that a particular cyclone would move in the direction of the upper wind, westwards.

Those who follow Clerk Maxwell's tradition will regret to see left-handed axes on pp. 196 to 197. There appears to be a mistake in the kinematic conditions at an interface between hot and cold air on p. 313. The treatment of turbulence on p. 125 still contains the idea that lumps of air, like molecules, have a "mean free path," although nothing of the sort has been observed in the atmosphere, and G. I. Taylor has provided a theory of "Diffusion by Continuous Movements."

Considerable attention is given (in Chap. xi. and elsewhere) to the ideas about sliding surfaces, which, after coming down from Helmholtz via Margules, Exner, and Ficker, have recently been brought into relation with rain, and with forecasting by V. Bjerknes and his associates.

Another important allied topic is the conversion of heat-energy into mechanical energy in the atmosphere. English readers will welcome the extensive account of the researches of Margules and of Sandstrom. The point of the present reviewer's work, on the supply of energy to eddies, is unfortunately quite missed on p. 186. With regard to the energy of cyclones, Exner writes (in the preface):

"The question of the energy of winds in our latitudes was treated in the first edition entirely in the sense of Margules' work. Since then I have come more and more to comprehend, particularly through the influence of Alfred Wegener, that the aforesaid energy comes originally from the unequal supply of heat to the lower and higher latitudes of the earth, that is to say, from large circulating currents, a change whereby Margules' calculations of course do not lose the least part of their value. But in the new edition it will be found that the rôle of the exchange of air between the tropics and the polar latitudes is made more prominent and that cyclones and anticyclones appear as conditions of this exchange. This conception cannot be brought into complete harmony with Bjerknes' view of the stable polar front and the wave theory of cyclones. . ."

Mr. W. H. Dines showed that the correlation between pressure and temperature was about 0.9 at 9 km., and decreased gradually as the earth was approached. Prof. Exner exhibits (Fig. 95) and explains this decrease of correlation as due to a shift of phase between waves of pressure and of temperature. We seem to approach again to a wave theory of cyclones.

There are numerous interesting and original features which we have not room to mention. The book is a sort of museum full of standard types, obtained by imagining in turn various different restrictions in order to make the differential equations integrable. These types resemble events sometimes to be found among the multifarious behaviour of the actual atmosphere, and they greatly aid us to understand what happens. They do not provide a continuous account of its day-to-day progress. No integral formulæ could. It is to be hoped that some publisher may be persuaded to issue an English translation of this excellent book. It does not attempt to summarise the researches by many authors published recently in England.

(2) In comparison with Exner's great work, this of Rouch is a simple popular book treating historically in clear French, without mathematics, the various forms under which the problem of weather forecasting has been proposed, from the earliest times to the present decade. The outlook is practical. There are diagrams showing Bjerknes' rain-areas, Gold's fifteen types of isobars, and Schereschewsky and Wehrle's cloud-system. The author estimates that, of the forecasts made nowadays by any method for one day ahead, not more than seven out of ten are justified by the event, and he considers that the fraction of success has not increased much during the last fifty years, owing to the inherent difficulties of the problem.

(3) In this astonishing paper, L. Weichmann, Director of the Leipzig Geophysical Institute, asserts that it has been proved from the barograms of stations in middle latitudes of Europe, Asia, and North America, that there are certain dates such that the preceding

part of the barogram is the mirror image of the succeeding part, the mirror being placed parallel to the pressure axis. Such reflections occur at

July 4, 1922, in North America; Jan. 1, 1914, in Russia Nov 6, 1923, in Hamburg, Jan. 15, 1924, in Hamburg.

The correspondence of the "incident" and "reflected" portions of the barogram is said to extend over months in time, and over areas on the map as big as continents

A number of barograms and weather maps are pointed in support of this contention; and the degree of correspondence is tested by correlating the corresponding pressures. After a slight judicious stretching of parts of the time-axis when the air was cold, the correlation attains the value 0.7. It is pointed out that a reflection will occur if all the Fourier component waves into which the barogram can be analysed attain their extremes at the same instant. Harmonic analyses have been made of pieces of the barogram including 180, 90, or 72 days. This was done after the stretching referred to above. It is shown that five or more component waves attain their extreme values at times which agree within ± 1 day.

The author does not give an estimate of the probability of this being a chance occurrence. We may get an estimate thus. Suppose many waves of period T_1 days, with phases at random. The chance of an extreme (*i.e.* maximum or minimum) lying within ± 1 day of a given instant is $4 \div T_1$. If there are four other periods, T_2, T_3, T_4, T_5 , with phases independently at random, the chance that these extremes should all lie within the chosen 2-day interval is $4^5 \div T_1 T_2 T_3 T_4 T_5$. That is to say, such an event would occur by chance on the average once in $2 T_1 T_2 T_3 T_4 T_5 \div 4^5$ days. On this reckoning the coincidence shown in Weichmann's Fig. 18 would occur by chance once in six years on the average, if the time-axis were not judiciously stretched, and presumably more often when, as now, judgment comes into play.

L. F. RICHARDSON.

Stellar Spectra and the Physics of Gases at High Temperatures.

Stellar Atmospheres: a Contribution to the Observational Study of High Temperature in the Reversing Layers of Stars. By Cecilia H. Payne. (Harvard Observatory Monographs, No. 1) Pp. ix+215. (Cambridge, Mass.: Harvard Observatory; Cambridge: W. Hefner and Sons, Ltd., 1925.) 2.50 dollars.

IT is announced by the Director of the Harvard College Observatory that, in addition to its Annals, Circulars, and Bulletins, the Observatory will from time to time publish Monographs dealing with subjects in which the Observatory is doing a large amount of

original investigation. Unlike the Annals, etc., the Monographs will not be distributed gratis to observatories and others, but special funds are available to enable them to be published at less than cost price. The first volume of the series is Dr. Cecilia Payne's "Stellar Atmospheres."

Astronomers will welcome not only the announcement itself but also the choice of the first subject, and their expectations will be fully justified by a study of Miss Payne's book. "Stellar Atmospheres" should immediately take its place as an indispensable handbook for the stellar spectroscopist who wishes to have easy access to the series classifications of the spectra he is interested in on one hand, and to the latest deductions concerning the temperatures and pressures in stellar atmospheres on the other. Miss Payne has brought to her task an enthusiasm and a thoroughness which, with the wealth of observations contributed by herself, make her book at the same time an attractive story and a work of reference. It may be mentioned that there are more than five hundred references to the original literature, of which more than half are to the sources of spectral classifications and determinations of critical potentials.

Part I. is a concise study of the physics of the atom as regards the origin of line spectra and of the physics of stellar atmospheres in so far as this is known independently of the methods initiated by Saha. An account is given of the colour temperatures of the stars, and of the various lines of evidence which indicate the order of magnitude of the pressure in the reversing layers of stars, following Russell and Stewart. A qualitative account of the probable structure of a stellar atmosphere is followed by a useful synopsis of the elements that occur in stellar spectra and the series classifications of the relevant lines.

The core of the book is formed by Part II., which is concerned with the physical interpretation of the observed features of stellar spectra. Six years ago, practically no explanation existed of why some lines appear in stellar spectra and not others, why some lines always decrease in intensity through the stellar sequence and others appear, reach a maximum, and fade away again. It is to Saha that we owe the key which has unlocked these mysteries. Saha showed that elementary thermodynamics, considered in connexion with Bohr's theory of the origin of spectra, demands that atoms pass through successive stages of ionisation as the temperature increases, and that they must necessarily produce just that sequence of absorption spectra which is observed in the stars. At the hands of Saha and others, this simple physical idea has received quantitative treatment which allows a wealth of detailed deductions to be made concerning pressures and

temperatures in stellar atmospheres from the observed intensity changes in stellar spectra

Miss Payne has devoted her own labours to this object. She has tabulated her own measures of line-intensities for the different spectral classes. She has then deduced the scale of stellar temperature, refining the standard procedure by a method which takes account of the differing levels at which lines originate.

An observed maximum of a line in the stellar sequence determines a certain relation between the temperature and pressure at the level in the atmosphere at which the line originates when at its maximum intensity. If the temperature be taken to be known from the colour scale, an observed maximum fixes the pressure. Theoretically the pressure is a complicated function of the relevant atomic and stellar quantities. Among other things, it might be conjectured to be inversely proportional to the maximum concentration of the atoms in the appropriate excited state—the stronger the concentration, the less deep we can see into the star in the frequency concerned and the lower the pressure. Miss Payne tests this conjecture and finds it to be reasonably well satisfied. She therefore uses the empirical relation to construct the temperature scale for the hotter stars, for which trustworthy colour-temperatures are wanting.

The fact that the product of partial electron pressure and relative concentration of excited atoms at maximum is approximately constant is of considerable significance. It will be one of the prime objects of theoretical astrophysics in the immediate future to remove the empirical character from this "constant" and to calculate it in terms of the ordinary atomic and stellar quantities. The "constant" will, of course, be found to be a function of surface gravity and atomic absorption coefficient, and the possibility will arise of measuring either " g " for the stars or the absorption coefficient for the atoms from observations of maxima.

Perhaps the most stimulating portion of Miss Payne's book is Part III., which deals with special problems. She lays special stress on the circumstance that the lines of Sr^+ are in many respects anomalous—for example, on the high-temperature side of the maximum they would be expected to be weaker in giants than in dwarfs, on the usual theory, whilst the reverse is observed. The reviewer would suggest that in this case the dominant factor is not the concentration of suitable atoms. In the steady state, the residual intensity in the principal doublets of Ca^+ and Sr^+ cannot exceed the values just capable of supporting the corresponding atoms against gravity. Surface gravity being weaker in giants than in dwarfs, the residual intensity must be weaker in giants than in dwarfs. Thus the lines must cut deeper into the continuous spectrum of the giant

than of the dwarf, and they may in consequence appear stronger in spectrograms.

It is perhaps to be regretted that Miss Payne has not adopted a linear classification of the O-type stars—for example, the one suggested by H. F. Plaskett. This leads to apparent anomalies in some of the tables—for example, a temperature of $35,000^\circ$ is allotted to type O from the maximum of the He^+ lines, a temperature of $25,000^\circ$ to the same type from the Si^{+++} lines. Reference to the tables of measures of actual O-type stars removes the apparent inconsistency, but the suggestion might be made that in a future edition a division of the absorption-line O-stars into sub-classes, even a provisional one, would be a help to the reader. This would be more consistent with the plan of the book, which is primarily concerned with the temperature classification of stars on the basis of absorption lines.

The treatment of the physical basis of the dissociation formula, first used in this connexion by Saha, seems to the reviewer unsatisfactory. The author appears to consider that Saha's own justification for the formula was merely analogy with physical chemistry, in particular the physical chemistry of dilute solutions, and that it was thus based on the law of mass action, that the acquisition of a charge at dissociation is the only feature that "chemical" and "thermal" dissociation have in common, and that thermal ionisation is a process different from ionisation by collision, for example. But thermal ionisation is not a process—it is an equilibrium state. The mechanism by which the final state is arrived at consists in part of photo-electric absorption, in part of ionisation by collision, and so on. Each of these processes in the long run will set up of itself exactly the same final equilibrium state. This final state is one which can be predicted by pure thermodynamics, save for a constant of integration, and the general dissociation formula was in fact given by Willard Gibbs in 1875 and applied by him to the "thermal" dissociation of gases such as N_2O_4 . It is, of course, possible to make some progress towards the deduction of the dissociation formula by using the law of mass action, but then any equilibrium-state formula can be deduced via reaction velocities. The final state is, however, known independently of any assumption about reaction velocities or of the mechanisms of decomposition and recombination. The only doubt in the original application of the dissociation formula to high-temperature ionisation was the value of the above-mentioned constant of integration—the "chemical constant" of the electron. Statistical mechanics adds nothing whatever to the validity of the dissociation formula. But it succeeds in going a little further—it actually evaluates the constant.

The spectroscopic notation used is that recently suggested by Russell and Saunders, and it proves very

convenient for the purpose. There is, however, some inconsistency in applying it to the Balmer series. Thus in one place the series is described as $(2P - mD)$, whilst elsewhere the line $H\beta$ is described as $(1S - 2P)$. Surely the Balmer series should be described as the superposition of $(2P - mD)$ and $(2S - mP)$.

Space does not permit an account of the many other interesting subjects studied in the monograph, but reference should be made to the astrophysical determination of ionisation potentials, and also to the chapter on the relative abundance of the elements in stellar atmospheres, which consists entirely of Miss Payne's own work on the subject.

Evolution and Popular Thought.

- (1) *The Earth Speaks to Bryan*. By Prof. Henry Fairfield Osborn. Pp. vii + 91. (New York and London: Charles Scribner's Sons, 1925.) 1 dollar.
- (2) *Concerning Evolution*. By Prof. J. Arthur Thomson. Pp. x + 245. (New Haven: Yale University Press; London: Oxford University Press, 1925.) 11s. 6d. net.
- (3) *Evolution in the Light of Modern Knowledge*. A Collective Work. Pp. xv + 528 + 4 plates. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1925.) 21s. net.

(1) **T**HE present widespread interest in evolution, largely due to recent events in the United States, manifests itself in the number of books addressed to the general reader which deal with evolutionary topics. "The Earth Speaks to Bryan" comprises five articles written for American newspapers and reviews apropos of the Tennessee anti-evolution trial. There is little doubt that, as Osborn believes, the trial has been a good thing for America. It has brought the chronic disease to a head and made the common people think about the whole issue. But in one respect it has had results which, to some at least, are not so desirable. So bibliolatrous is the general temper of many American States, and so anxious have some American men of science been to show that the teaching of evolution is not, as Mr. Bryan amazingly put it, essentially atheistic and immoral, that they have gone to the opposite extreme and tried to reconcile evolution and the Bible in every particular, and to gloss over the real differences which are inevitable between the supernaturalism of a revealed religion and the naturalism of modern science. Osborn seems to be in this category. He confuses religion with theism and apparently with Christianity, and belief in the soul as a psychological tenet with a belief in "the reality of moral and spiritual values." He goes so far as to say that the "proof," which he asserts has been furnished by palæontology, of the non-

fortuitous nature of variation (as to which proof most biologists would be in disagreement with him) brings us back to find Paley's argument for the existence of God "just as strong as ever it was" in pre-Darwinian days. He, of course, asserts that "God used evolution as his plan," as if this were self-evident, and actually states that the Bible is an "infallible (*sic*) source of spiritual and moral knowledge."

The merit of the book is its easy and vigorous style.

(2) Prof. Thomson has an equally easy style, but it sometimes has rather a fluffy effect. Perhaps he is too open-minded, and tries to do justice, a little too liberally, to everybody's views all round: and perhaps he writes too many popular books to preserve his native terseness. Otherwise his volume is an admirable summing-up, not too technical but not too popular, not ultra-modern and yet not old-fashioned, of his view of evolutionary biology. He also tries a fall with the old problem of religion and science, and comes to the characteristic conclusion that each is right in its own sphere. But when he says, "there is no possible way in which Science could disprove God," he has not concerned himself to point out that though this is in one sense a truism, yet science can disprove, and has disproved, many gods, and many assertions as to the attributes of God. As usual, Prof. Thomson is especially interesting in regard to animal behaviour.

(3) The third volume is by far the most ambitious. It contains contributions from thirteen scholars on different aspects of evolution, from cosmogony to anthropology, from physics and chemistry to philosophy and religion. Canon Wilson, in one of his broad-minded and reverent articles, traces the influence of the evolutionary theory on his mind from the time of the appearance of the "Origin of Species" (when he was already the science master at Rugby School!), through a period of doubt, to a new form of belief. It is interesting to hear that his mature belief took its source in reflections on the human spirit. This is religious naturalism, though the form of his belief be very different from that of many others who would start building their religion upon naturalistic foundations.

We are glad to see an article by another G.O.M., Prof. Lloyd Morgan—a sane and mellow article on general biology and the relations between mind and matter, with an interesting brief summary of the writer's views on emergence in evolution. Dr. Pembrey's article on physiology is interesting in itself, and also as showing how the influence of the theory of evolution upon this branch, at one time much less than that upon morphology, is to-day very strong, just at the time when many zoologists are hypercritical on

evolutionary matters. His discussion of the inheritance of acquired characters is vitiated by a certain vagueness consequent upon his taking no account of modern genetic work. Prof. McDougall has a rather sketchy article on mental evolution, and Prof. Taylor writes a long and not always easy essay on philosophy and evolution. At one point he makes the slip (p. 448) of omitting all the "orthogenetic" side of evolution, which has been emphasised in different ways by men so different as Huxley and Eimer, Osborn and Morgan. Prof. Soddy sums up evolution in physics and chemistry, but with very little reference to theories of cosmogony. Because now the only changes we can detect in the elements are degradative, that is no reason why in wholly different conditions, for instance of temperature, progressive and truly evolutionary changes in inorganic matter may not have occurred. Prof. Elliot Smith has a provocative article on anthropology. At one time he uses biological analogies in support of his theory of the spread of culture, while later he stigmatises such procedure as dangerous and misleading. It is rather amusing to find him laying down as obvious that similarity implies common descent, while in the same volume Prof. Bower in his article on botany is cautiously coming round from this to the idea of a parallel development in a whole group like ferns! We would also remind Prof. Elliot Smith, first, that Wheeler has made it clear that the social habit of ants, bees, and wasps has been acquired independently for each, and probably more than once in some of the three groups, and secondly, that the work of the Morgan school is showing that parallel mutations may occur independently in different species (e.g. of *Drosophila*, etc.). It behoves anthropologists, whose material is vaguer than that of the systematist, to walk rather more warily than they (or some of them) are, at present in the habit of doing.

Prof. Bower's article is rather more technical than most, and will be of more interest to biologists than to the general public. Prof. MacBride enters his usual plea for Lamarckism. It might be wise to lay less stress on Tornier's work as "proving" the inheritance of acquired characters and the origin of mutations, considering that it was never taken beyond *Fr!* The "indirect proofs of the inheritability of the effects of habit" are not proofs at all; and the remarks about mutation are very one-sided. At the close Prof. MacBride commits himself to the definite statement that the typical larva of molluscs and annelids represents an ancestral form, whereas it is at least equally probable that it is a special adaptation to dispersal, and there is, in the absence of fossils, no means of deciding which view is right!

The excellent articles by Drs. Jeans and Jeffreys on cosmogony and the evolution of the earth as a planet will be read with special interest, because of the great advances which have recently been made in these fields.

The book is in many details interesting. However, it can scarcely be said to fill the gap mentioned in the preface—the want of any recent authoritative statement on the subject of evolution by British naturalists. Too many of the writers have axes to grind in the shape of pet theories, and there is not enough of a central scheme running through the book, so that the articles are heterogeneous in nature. But it contains plenty of good reading, both for layman and man of science.

University Calendars.

The Calendar of the London School of Economics and Political Science. (University of London) for the Thirty-First Session, 1925-26. (London: London School of Economics and Political Science, Houghton Street, Aldwych, W.C.2, 1925.) 3s. 6d.

THE aim of a university is to supply information to its students, to train their intelligence, and to render them capable of doing and making things in the best way. This doing and making being the ultimate aim of a university education, it is not unreasonable to inquire into the success of a university when it is itself engaged in doing or making. A university does not often give the chance of this test, but every university does every year produce one book, its university calendar.

The members of a university do not inquire whether their own calendar is a satisfactory production. It may be that even the least patient of us can ascertain the contents of one ill-arranged book; it may be that a university has a few experts who make the information available for the rest; it may be that the handing down of the facts by oral tradition makes the study of the calendar unnecessary.

It is the man who has to study university calendars in bulk who is really in a position to see their merits and defects. Such a man, when he has to ascertain some point about a university, turns to the index of the calendar. In many cases the word sought does not appear in the index; in other cases it is there and gives reference to a number of pages none of which contain the information desired. The man then tries the index for all other possible keywords, but frequently with no better success. The investigator next turns to the table of contents. He tries first to ascertain the general arrangement in order to see in which division his point is likely to be found. There is usually no orderly arrangement. The principle of the calendar is often

that of the dust-heap. When anything has to be added to the calendar it is simply dumped on the top of the stuff already there. The investigator is thus compelled to read through the table of contents until he finds a likely item. The descriptions in the table are, however, so colourless and so inappropriate that he has to study quite a number of likely and unlikely items before he finally runs to earth the information he is pursuing.

There is probably no man in the United Kingdom who has more occasion to study university calendars than the present writer and three of his colleagues; and the foregoing description gives their experience down almost to the present day. The calendars of universities and colleges have hitherto shown such a dead level of badness that it has not been possible to pick out one as being either worse or less bad than the rest.

That time of dead uniformity is past. There is now one calendar that has evidently had some of the attention that an author is accustomed to bestow on his book. It has an index that functions; related portions are brought together; the table of contents gives evidence of an orderly arrangement; and the titles used for the various portions are reasonably descriptive of the contents of the portions. In the average calendar the title-page is lost among a mass of advertisements or other misplaced matter, and the beginning of the text is similarly concealed and has not the smallest fraction of a page left blank to show it up; so little do æsthetic matters appeal to the ordinary university. The calendar of the London School of Economics for the current year has a title-page at the place where one naturally looks for it, and by the use of appropriate type for the titles of divisions and subdivisions it shows up the orderly arrangement of the text. It has, in fact, some of the attractive traits which we expect to find in all proper books.

This calendar does not yet show much appreciation of æsthetic values. It would be improved by a more generous allowance of blank paper at the head of a page on which a chapter begins. The use, also, of appropriate blanks between sections of a chapter would have æsthetic value, and at the same time add to the clearness of the general plan of the calendar. The first step in reform has, however, been a long one, and we may hope that further steps will be taken, and that æsthetics will presently come into their own.

Some people uphold economics as a better training for most walks in life than the older studies. On that we express no opinion beyond inquiring whether it is a mere coincidence that this school of economics, which is not half a century old, should have been able to make of this calendar a pleasing book with its informa-

tion readily accessible, while the universities that have had centuries of experience in the production of calendars still give us the kind of abortion described above. However that may be, the wise university will study the calendar of the London School of Economics and see if it cannot do something on the same lines.

Financing Agriculture in North America.

Farm Credits in the United States and Canada. By James B. Morman. (The Rural Science Series.) Pp. xvi+406. (New York: The Macmillan Co., 1924.) 15s. net.

UNTIL the establishment, under Federal auspices in 1916, of the land banks and joint-stock land banks, the farmer in the United States obtained loans mainly from commercial sources and life insurance companies. The book under notice is a careful review in simple language of the gravely important consequences of the changes in the methods of obtaining credit facilities which these banks have introduced. The success of the land bank system, with its fixed maximum rate of interest, its appreciable reduction in the initial charges to the mortgagee, and its scheme for gradual repayment of the sum advanced, is evidenced by the value of mortgages taken out. In six years they have amounted to 90 per cent. of those accumulated in the life insurance companies in all their existence, which in some cases is more than fifty years.

This "success" is, in the author's opinion, a mixed blessing. Advances are much more easy to obtain, and although a farmer may obtain temporary relief from immediate embarrassments, he has nevertheless taken on an additional burden. It is not so much the interest as the debt itself that is the real trouble. Whether the debt be repaid in annual instalments or as a lump sum, the burden is intensified with lapse of time because of capital depreciation, a factor seldom considered by the farmer when negotiating the mortgage. Most forms of capital equipment are worn out or reduced to a nominal value in ten years, and unless depreciation has been allowed for, the farmer may find the temporary alleviation of his difficulties has, in the long run, intensified them. Even with the more equitable terms of the land banks, in which the provision for gradual repayment of mortgage is perhaps the most important, the proportion of failures to meet obligation is increasing.

The heavy load of debt is undeniable, and the author considers that for many years to come, United States agriculture, as a whole, will have to carry the heaviest financial burden of any industry, and this

in spite of the fact that more than 50 per cent. of owner-farmers are free from debt. It is satisfactory to record that Canadian systems of credit—especially short-time credit—receive favourable comment.

The most significant statement in the book is that mortgage credit agencies, however beneficial their intentions, are not to be compared in their usefulness and service to farmers with the agricultural colleges and experiment stations throughout the country. These institutions are helping the farmer to increase his income in various practical ways, and if they cannot rescue him from the dilemma in which he finds himself as the result of easier mortgage credit terms and conditions, he will find no relief anywhere. In view of the author's position of economist on the Federal Farm Loan Board, this considered statement of the limits of direct financial aid to agriculture must carry great weight.

Although the book does not discuss British conditions, it contains the material for useful analogies, as well as much of direct interest to agricultural economists on the eastern side of the Atlantic.

Our Bookshelf

Abridged Scientific Publications from the Research Laboratories of the Eastman Kodak Company Vol. 8, 1924. Pp. 155 + vi. (Rochester, N.Y.: Eastman Kodak Co., London: Kodak, Ltd., 1925.) n.p.

THE Research Laboratories of the Eastman Kodak Company have been in full working order for about twelve years, during which time investigations have been carried on by the staff, not only on matters directly concerning the practice of photography and the manufacture of the materials and apparatus required for it, but also on various chemical and physical matters that appear at first sight to be rather remote from this subject. Time will doubtless justify this wide view of what is desirable. The results are published in numerous scientific journals as may be suitable in each case, but the papers, slightly abridged, are all brought together in the series of volumes of which this is the most recent.

This volume contains full and often lengthy abstracts of the 28 papers published last year. Many of these have already been referred to in our columns, and others are of interest only to the manufacturers and users of films for "motion pictures." Mr. F. E. Ross has dealt with the mensurational characteristics of photographic film, because film is now used for so many scientific purposes where the sensitive surface must be flexible. It appears that, generally speaking, films may show no greater distortion than glass plates, and that the different kinds of film vary somewhat. The relationship between time and intensity of illumination in photographic exposure is investigated in considerable detail and under considerably improved experimental conditions as compared with earlier work on this subject, by Messrs. L. A. Jones and E. Huse. Messrs. A. B. Corey and H. Le B. Gray, in seeking to prepare a

standard cellulose, find that by treating the product obtained as described in a previous communication with 1 per cent. acetic acid solution for two hours and subsequent washing, the ash is reduced to a very low quantity without apparent injury to the material. The reduction is stated to be "from 0.12 to 0.4 per cent." This misprint and a figure upside down at p. 16 show that more revision is desirable.

- (1) *A Laboratory Manual of the Anatomy of the Rat.* By Prof. Harrison R. Hunt. Pp. viii + 123. (New York: The Macmillan Co., 1924.) 6s. net.
- (2) *Laboratory Manual of the Foetal Pig.* By Prof. W. J. Baumgartner. Pp. xii + 57. (New York: The Macmillan Co., 1924.) 4s. 6d. net.

THESE manuals have both been written as guides to mammalian types which have been found suitable for laboratory purposes in the two universities at which the respective authors are engaged in teaching zoology. The use of the foetal pig as a type for dissection must of necessity be limited to universities and schools situated in towns, such as Chicago and Kansas, where packing plants are available as sources of supply, but the use of the rat has wider possibilities, and, for that reason, Prof. Hunt's manual will be specially welcome in Great Britain. Prof. Baumgartner's manual is modelled on Marshall and Hurst's "Practical Zoology," that is to say clear directions for dissection are picked out in italics throughout. Prof. Hunt, on the other hand, has chosen to give a more or less connected account of the various systems and organs of the rat in which instructions for dissection are given in their appropriate places, but only incidentally. The former style has so many advantages in a book designed for the use of students that one almost regrets that Prof. Hunt did not adopt it for his book, particularly as it is almost sure to have a wider field of service.

A serious defect in both books is the absence of illustrations. This is deliberate on the part of Prof. Hunt, who believes that it is better for the student to get his visual impressions from the animal itself. While appreciating this point of view, it cannot be doubted that clearly reproduced figures are a wonderful aid to dissection and are worth many pages of the most carefully written text. The authors may, perhaps, reconsider the question should further editions be called for. The addition of figures would enhance the usefulness of these two excellent manuals enormously.

The Psychology of Emotion, Morbid and Normal. By Dr. John T. MacCurdy. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvi + 589. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1925.) 25s. net.

THE author expresses a hope that his readers may be drawn not only from psychiatrists and psychologists but also from laymen interested in psychological problems. If this hope be fulfilled, the ranks of the former will be recruited from the latter. A person who has read and understood this book and studied the work of the authorities referred to in it can scarcely be styled a layman hereafter. Should he find his interest flag, the short but excellent chapter on treatment may be relied on to revive it.

As may be surmised from these observations, the book is a comprehensive one. To fortify his thesis the author gives stimulating reviews and criticisms of the work of C. Lange and William James, of McDougall, Freud, Janet, and Morton Prince, in so far as they have concerned themselves with emotions. He includes full studies of states of anxiety, mania, stupor, depression, and perplexity, illustrated by detailed notes of some seventy cases. The thesis in question is, that emotion, both as regards its expression and its feeling-tone (or affect), is the product of mental processes occurring co-consciously, co-conscious being the term applied to unconscious mental processes in a state of activity.

The methods and reasoning by which this conclusion is arrived at cannot be compressed into a short notice, but accompanying Dr. MacCurdy along his psychological and psychiatric highways and byways is an interesting journey. On page 571 he states that "a particular grouping of words will excite a stylist pleasantly or unpleasantly." Some of the "Americanisms" in "The Psychology of Emotions" may produce the latter effect on the English stylist, but they do not detract from the value of the work as a whole.

The History of the English Novel. The Age of Romance. from the Beginnings to the Renaissance By Dr. Ernest A. Baker. Pp. 336 (London H. F. and G. Witherby, 1924.) 16s. net.

DR. BAKER takes a broader view of the origins of the English novel than is customary. He links it up not only with prose fiction of the Middle Ages, but brings it into relation with much of the material with which the student of the folk-lore and cultural history of Great Britain has to deal in the form of popular tales, legends and romances. His book, therefore, appeals to a wider public than that which is interested only in literary history. He passes beyond early prose fiction in Great Britain, touching upon its complement in France and Brittany, and goes back to early Greece, the connexion being traced through Euhemerus, the paraphrasts of Homer, and the later Greek and Latin writers of romance. To those who hold the view that the study of the folk-tale in Europe is largely a matter of literary history, Dr. Baker's investigation of sources and, perhaps in particular, of Anglo-Saxon fiction, will prove suggestive. In dealing with the Arthurian cycle, he covers ground which has been made familiar by the work of Miss Jessie Weston, Dr. Oskar Sumner, and, above all, the late Sir John Rhys; but his later chapters, dealing with other or later romances and with popular tales and *fabliaux* such as appear in the "Gesta Romanorum" and other collections, form a useful guide in a maze much of which, though not untrodden, is as yet inadequately explored. Dr. Baker's work shows wide reading and sound scholarship.

The Fats. By Prof. J. B. Leathes and Prof. H. S. Raper. (Monographs on Biochemistry.) Second edition. Pp. vii + 242 (London Longmans, Green and Co., 1925) 12s. 6d. net.

THE appearance of the second edition of this monograph, after a lapse of fifteen years, will be welcomed by all those interested in the subject. The author of the first edition, Prof. J. B. Leathes, has collaborated with Prof. H. S. Raper in the re-editing and re-writing of the present volume. The first three chapters are devoted

to the chemical and physical properties of the fats, with methods for their extraction and estimation. The remaining seven, a lengthy expansion of only a short section in the first edition, deal with their physiology and give an up-to-date and reasoned account of the parts played by them in both plant and animal tissues. The stages in their digestion, synthesis, and utilisation are fully described as far as present knowledge permits; the transport of fat in the blood is considered in detail, and a reasoned criticism of Bloor's deductions from his experimental results put forward. The last chapter deals with the rôle played by fats, apart from their function as a source of energy, in the life of the cell; they form an integral part of the structure of protoplasm, and modern work already suggests possible ways in which their molecules may be arranged therein. The work is completed by a bibliography and index.

Organic Medicaments and their Preparation By Ernest Fourneau. Authorised Translation by W. A. Silvester. Pp. x + 262 (London J. and A. Churchill, 1925.) 15s. net.

IT throws an interesting light on the working of the British educational system that although French is taught in practically every school above the elementary rank in England, it should still be thought necessary to issue English translations of French books. The French edition of M. Fourneau's book has already been reviewed in NATURE (July 15, 1922, p. 50), and the opinion there expressed that it "should find a place wherever organic chemistry is taught to advanced students" is heartily endorsed by the present writer.

Mr. Silvester has done his work well and the terseness, clarity, and precision of the original have not suffered in his handling of the text. He has taken the opportunity to add a short but well-selected bibliography, which will be useful to those unfamiliar with the subject, and notes are appended here and there throughout the text directing attention to recent developments. The French edition was issued in 1921, and it says much for M. Fourneau's skill in the selection of material that the translator has been able to bring the English edition up-to-date with so few additions of his own.

T. A. H.

Wales: an Economic Geography [By L. B. Cundall and T. Landman. Pp. x + 364. (London George Routledge and Sons, Ltd., 1925) 6s.]

THE authors have taken pains to collect and arrange their material for this geography of Wales, the first of its kind to be published. They have interpreted their subject liberally and succeeded in producing a full and accurate volume, which has the further advantage of being interesting and readable. Several of the chapters, such as those on coal and non-ferrous metals, take a wide survey of the whole subject, and might well be read by those to whom the details of Welsh geography are of minor importance. A further advantage of the book is that the historical side of industrial activity is kept well in view, so that a very clear picture is gained of the evolution of Welsh industries and towns. Statistical matter is freely used, and there are even appendices giving the trade terms used in the coal and other industries. The index is full, but might be revised in a later edition.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Conditions of Chemical Change.

PATIENCE has its limits and modesty may be overdone. I am moved to these reflections by a three-page note in the Journal of the Chemical Society to hand to-day. I am carried back forty years, to a meeting at the society, in March 1885, when a shy Oxford graduate, a worker in Mr. H. B. Dixon's laboratory, told us practically that charcoal and phosphorus could not be burnt in dry oxygen. Actually, he told us less, as he did not then go nor has he since gone beyond his facts. That, however, was the inference to be drawn from his work, taken in conjunction with that of Cowper, Dixon, Wanklyn and others, on the effect of drought in checking chemical interactions. I there and then stated what I will now venture to term the *theory* of chemical action, chary as I am always of using the word, if there be the least reason to rest more faith in honest doubt than in a creed. In a sentence, that theory is, that chemical action, of whatever kind, is essentially electrolytic: consequently, change takes place only when the potentially interacting substances constitute an electrolytic circuit: such circuit appears always to be one of three components, of which one, necessarily, is an electrolyte. I was, therefore, able to say that hydrogen and oxygen would not and could not interact; further, that even when "wetted" they would not interact, as water was not an electrolyte: only when the water was made "conducting" by the presence of a dissolved "salt," would change be possible.

Several years later, by further exact experiments, Baker demonstrated the truth of these propositions. He developed an uncanny ability in "drying" things, and proved, in numerous cases, that the conditions I had laid down were essential to the occurrence of change. Others have verified some of his observations. About three years ago, however, Coehn and Tramm questioned his work and stated that hydrogen and oxygen not only interacted, under the influence of the light from a quartz-mercury lamp, but at the same rate whether the mixture were dry or moist.

Talking the matter over with Baker, I said: "Yes, as interaction takes place in a liquid film, at the surface of the containing vessel, ultra-violet light, at a low temperature, may well have a greater effect than heating, in bringing about change. Persevere in cleaning and drying the vessel and its contents and action will be stayed."

Baker now reports, that in a quartz tube which had been dried during twelve weeks no measurable action was observed during an exposure of thirteen hours to a quartz-mercury lamp at a distance of 2 cm., although action took place in tubes less thoroughly "prepared."

Baker and I have wandered all but alone these forty years in an arid wilderness, athirst for recognition and sympathy. I feel that we must now compel this, and that we have the right to challenge all and sundry, chemists and physicists alike, to consider the grounds of their belief, if they have one. When the history of our time comes to be written, nothing will appear more striking than the strange psychology of the "scientific" worker so-called: particularly the

way in which he was captured by the wild Arrhenic speculation, more especially by Ostwald's dogmatic rulings. After all, he has but shown that he is human and dominated by the herd-instinct. Many may be called into "science," but few are chosen—to think for themselves and behave as reasoning beings. Still—

One must receive their nature in its length

And breadth, expect the weakness with the strength!

Sordello.

The issue I raise is of consequence at a time when so much importance is attached to the determination of ionisation potentials in gases and so much argument is based upon the values deduced—but no attention whatever paid to the conditions prevailing in the vessels used. Neglectful as is the chemist, the physicist is far worse: seemingly he has no conception of chemical cleanliness, and the chemist, in consequence, often takes leave to doubt not a few of his deductions. It was not always so—it was not so when chemistry was taught together with physics. Of late years, we seem to have sought how not to teach the various branches of science effectively—by teaching them singly and encouraging a crass specialisation, which is leading us to neglect and fail in solving the problems of real importance.

HENRY E. ARMSTRONG.

October 1.

Haploidy in the Male Sawfly (Tenthredinidae) and some Considerations arising therefrom.

IN 1907 Doncaster published certain statements on the gametogenesis of the common gooseberry sawfly, *Nematus ribesii* Scop. ("Gametogenesis and Fertilisation in *Nematus ribesii*," *Quart. Journ. Micro. Sci.*, vol. 51 n.s., 1907), but later, in 1909, he published a correction (*ibid.* 1909. "Gametogenesis of the Sawfly *Nematus ribesii*. A Correction." *NATURE*, Dec. 2, 1909, p. 127). Unfortunately, he never resumed the investigation, and the problem was so left that its solution demanded work *ab initio*. Since then, nothing further has been done to elucidate the question, but work done by me on the spermatogenesis of the sawfly *Pteronidea melanaspis* Htg., together with certain breeding experiments with *Pteronidea* (*Nematus*) *ribesii*, permits certain pronouncements which throw considerable light on the subject.

Doncaster's material and mine belong to the same genus,¹ and the two species behave alike sexually in that the females, by parthenogenesis, produce males only (arrhenotoky), whilst, after insemination, they produce both sexes. These reproductive habits are likewise common to a great many sawflies, and indeed, except possibly for one species only, we may lay it down as a principle that for all bisexual sawflies in which the sex-ratio is normal (about 100:100), parthenogenesis results in the production of males only.² Any conclusion concerning *P. melanaspis*, therefore, will apply most probably to all such arrhenotokous species.

The cytological results for *P. melanaspis* are:

1. The spermatogonial chromosome number is 8 (Fig. 1);
2. The spermatocyte chromosome number is also 8 (Fig. 3);
3. There are two maturation divisions in spermatogenesis, but no reduction in chromosome number (Figs. 4 and 5);

¹ *Nematus ribesii* now is called *Pteronidea ribesii* according to Enslin's classification.

² The experience of sawfly workers, notably Miss E. F. Chawner, shows that the list of arrhenotokous species will be greatly increased by further work, and indicates also that all bisexual sawflies are facultatively male-producing by parthenogenesis. Occasionally a female is produced, but this occurrence raises questions which cannot be discussed here.

4. No abnormal methods of cell division, such as described in the spermatogenesis of the hive bee and hornet by Meves and others, have been discovered;

5. The above hold good for males obtained from parthenogenetic females and from wild larvae collected in the field.

The technique employed, fixation by Carnoy or Bouin, with the usual succeeding operations and staining by iron-haematoxylin, has given excellent results, so that the cell appearances are perfectly plain.

These findings lead to the following inferences. As the spermatogonial chromosome number of the male is 8, the somatic number is likewise 8. It follows that 8 is the haploid number, and that the male sawfly produced by parthenogenesis, in arrhenotokous species, is haploid in constitution.

Immediately, the further important question suggests itself: if the parthenogenetically produced

PTERONIDEA MELANASPIS.

All figures drawn to same scale, using a Leitz microscope with a 10 periplanatic ocular and a $\frac{1}{2}$ oil immersion objective and a Reichert drawing apparatus. Cytoplasmic appearances and cell outlines largely lost owing to the material being fixed with Carnoy's fluid.

FIG. 1. Group of spermatogonial plates with chromosomes up to 8 in number.

FIG. 2. Spermatogonial mitosis.

FIG. 3. Chromosome plates of spermatocytes of the first order: two show 8 chromosomes and one shows 7.

FIG. 4. Equational division in spermatocytes of the first order.

FIG. 5. Plate of 8 chromosomes and phases in the division of spermatocytes of the second order.

Note, the differences in the sizes of the chromosomes and plates of the first and second spermatocytes.

sawflies of bisexual species are both haploid and male, are the males from inseminated females of such species likewise haploid and really of parthenogenetic origin also? That is, do bisexual species of sawflies follow a plan similar to that of the hive bee in which the queen, by controlling the fertilisation of the egg, produces diploid, fertilised, female-producing eggs, as well as haploid, unfertilised, male-producing eggs; or, if this be not the case, do they conform to the general rule among bisexual insects (except lepidoptera) that inseminated females give diploid and homogametic females and diploid and heterogametic males? That the former is the case is the main point of this letter.

These questions could be solved at once and directly if we knew the chromosome constitutions of such female sawflies and of the males produced by them after insemination. Unfortunately, the material from collected wild males does not provide complete information on such, but, nevertheless, an answer can still be obtained indirectly in another way, as will be seen presently, from certain breeding experiments.

The argument is as follows, and it is based on the assumption that the female sawfly is diploid and homogametic and therefore produces only one kind of germ cell—the haploid sort. This assumption is perfectly justifiable in the light of present knowledge; but its truth will be tested for the purpose of this discussion.

For example, let us suppose that the chromosome number of all parthenogenetically produced male sawflies of a given species is $n+x$, x representing the sex chromosome condition. The female, therefore, would have a diploid constitution of $2n+2x$, and would produce eggs of only one kind having the haploid chromosome number of $n+x$. Unfertilised eggs, by parthenogenesis, would of course give haploid offspring, which would be males, while the fertilised eggs would have the diploid number of $2n+2x$ restored and so yield females.

Let us now test the possibility that males produced by inseminated females have a chromosome constitution different from males produced by parthenogenesis, i.e. that there are two different kinds of males, haploids and diploids. Such diploid males, produced by the union of male and female gametes, according to present convention, would be designated $2n+x+y$ (y representing that sex chromosome possession of which determines maleness). A male would therefore produce gametes of two kinds constituted $n+x$ and $n+y$. The union of a male $n+y$ gamete with a female $n+x$ gamete would give an organism of complement $2n+x+y$, that is, a male: the union of a male $n+x$ gamete with a female $n+x$ gamete would always give an organism of $2n+2x$ complement, that is, a female. But, and here is the important point, my experiments (unpublished) with *Pteronidea* (*Nematus*) *ribesii* controvert the latter consideration, because parthenogenetically produced males, $n+x$ in constitution, mated with females, induce the production of both sexes.

Clearly, then, as the gametes from parthenogenetically produced males are all alike, the diversity in the results of pairing depends upon the female; further, this diversity can only be explained in three ways, either (1) the female controls egg fertilisation, or (2) the female is digametic, or (3) the parthenogenetically produced eggs of $n+x$ constitution are different from the $n+x$ eggs of the fertilised females. The second hypothesis is untenable for the critical reason that its consequence would be the production of two kinds of males by parthenogenesis, and we know from the above cytological results that this is not the case. Again, all female insects, except lepidoptera, are homogametic. The third hypothesis may also be dismissed, for all our knowledge to-day, and it is very considerable, on animal cytology proves that identity of chromosome constitution in eggs results in the identity of their end products, provided, of course, that the conditions of development are normal and alike.

We are left to conclude, therefore, that the inseminated female sawfly of bisexual species controls the fertilisation of its eggs, the unfertilised eggs yielding males and the fertilised eggs females.

Additional support to this thesis is obtainable from other sources, as, for example, the fact that other hymenoptera such as bees, wasps, the parasitic wasp *Hadrobracon* (Whiting) and the cynipids (*Doncaster*), behave in this way. Further, in the very species which has been cytologically examined, *P. melanaspis*, the very fact that the wild male larvae have the same chromosome constitution as the pedigree parthenogenetic males is very significant, for, even if these wild larvae were offspring of an unfertilised wild female, it is an indication that they are utilised in Nature as, certainly, similar larvae of *ribesii* are utilisable

because they have been successfully paired with females in the laboratory and offspring of both sexes have resulted.

There can be no reasonable doubt, therefore, that all sawfly males are of one kind in that they originate from unfertilised haploid eggs which may be laid by virgin females or by inseminated females.

This finding affords a clue to other problems of sawfly parthenogenesis and its evolution, but these will not be explored at this juncture, their discussion being deferred for the paper, now in preparation, which is to deal, in detail, with the matter of this letter together with other features of sawfly spermatogenesis.

It remains to make grateful acknowledgements to the British Association for a grant in aid, and to the following, all of Armstrong College: The Research Endowment Fund Committee for the provision of a Leitz Binocular Microscope, Prof. A. Meek for the facilities of his zoological laboratories, including the services of the steward, Mr. D. C. Geddes, and Dr. J. W. Heslop Harrison, who checked my cytological conclusions.

A. D. PEACOCK.

On the Advancement of Science by Published Papers.

UNDOUBTEDLY science is kept alive by teaching; and without good teaching, there can be but little discovery. Edison, for instance, when young, possessed and studied Faraday's masterly researches on electricity.

The present writer has been engaged in scientific research for eighteen years or so. He does not pretend, however, to have observed all the following rules, of the importance of which he became cognisant by degrees. The foundation of the co-operative fabric of science and scientific discovery has been built up by the work of the early "missionaries of science," when research entailed more or less of a martyrdom. It is hoped that we can pass on to posterity this edifice of science, undecayed and even embellished, now that research is a privilege and a giver of prestige. If we do not, the position of science and scientific work may deteriorate without limit.

(1) The truth, and nothing but the truth, but never the whole truth *for publication*. One must omit trivialities. Our scientific magazines are now sometimes more or less packed with never-to-be-utilised details, most of which perhaps would have better rested in the notebook. The penalty for non-observation of this rule is the, probably now imminent, cessation of publication, except in the form of abstracts.

(2) It is perhaps unethical for a research worker, as for a medical man, to advertise. Plethoric papers, pictures not absolutely necessary, repetitions in different magazines, references mainly to one's own work, and unneeded elaboration or enlargement of figures, seem to partake of the nature of advertising. The penalty for infraction is the introduction of competitive business methods into science as an ideal; instead of the co-operative aims, which have produced such good results in the past.

(3) Mere facts, however new, are often (though not always) of perceptible scientific value only when their discoverer, or some one else, has demonstrated their relations to other facts, or to a theory or hypothesis of value. If they have no such demonstrable relations, they are probably "trifling though true." The penalty is again the ending of magazine publication *in extenso*.

(4) The repetitions and confirmations of a discovery on similar or related material are of sufficient scientific interest to warrant full publication only to a certain degree of repetition. Whether this is ten or a hundred times, the point is at length reached when only the accounts of exceptions to the rule are worth full publication. The penalty is again the flooding of magazines, and the future reduction to abstract publication.

(5) The publication of a working hypothesis by one who has discovered a sufficient amount of relevant fact is welcome, and indeed almost necessary. (A working hypothesis is one that is immediately to be tested.) But a mass of untested hypotheses is readily producible; and may be aimless, except to fill space. A flood of hypotheses, which cannot be immediately tested, may be a brake on the progress of a science. Since it is easier, for many of us, to spin hypotheses than to make discoveries, the penalty for the appreciation and prestige of this form of mental exercise is the partial, or even complete, cessation of experiment.

(6) It is probably unethical to claim credit or priority for an untested hypothesis (mostly for writers in the distant past), to the prejudice of those who have borne the full burden of testing it. A writer who has published, among a number of unworkable hypotheses, one which has subsequently been used as a successful working hypothesis, does not apparently deserve to be cited. Perhaps one should not attach priority to *any* untested hypothesis, but only to true working hypotheses.

(7) It is generally recognised that, in a serious scientific paper, citations of a genuinely relevant previous work should be complete, so far as they are not known to all readers. Even excessive and pedantic citation is a fault on the right side. But surely much space might be saved by referring to standard numbered annual lists of scientific papers. The penalty for lack of citation is, of course, to leave it doubtful as to how much the writer has himself discovered. It leads also to the isolation of workers or countries. But excessive citations again overload the magazines.

(8) A form of scientific co-operation consists in the sending of separate copies of papers, in not readily accessible magazines, to other interested workers. This has now extended to all magazines, even those accessible to everybody. Stanley Hall regards it as a means of working up a personal following or constituency; in other words, it is now an advertising method. Perhaps as much as anything else, it injures the circulation of the scientific magazines.

These and other similar rules are, of course, well known to, and observed by, many experienced workers.

JOHN BELLING.

Huntington, N.Y.

The Band Spectra associated with Carbon.

IN an interesting letter to NATURE (August 8, p. 207), Prof. Birge has directed attention to a band system which I described as a "New Band System" in Proc. Roy. Soc., A, vol. 108, p. 349 (1925). More recently (NATURE, Sept. 5, p. 360) M. Baldet has written with reference to this system, pointing out that three of the six bands I recorded were measured and described by him in C.R., vol. 178, p. 1525 (1925). I should like to take the opportunity of saying that at the time of writing my paper I was not aware of this work of M. Baldet, and to him must be given the credit for the first recorded measurements of the system. At the same time, the discovery of this spectrum was first recorded by Prof. Merton and myself in Proc. Roy. Soc., A, vol. 103, p. 389 (1923),

as follows: "It should be remarked that in addition to the Comet-Tail bands which are degraded to the red, there are a number of very much fainter bands which are degraded to the violet, but are somewhat similar in appearance." Under the conditions of production in helium mixtures, this spectrum is isolated along with the comet-tail bands and negative carbon bands from all other band spectra which might conceivably have rendered the identification from this brief description uncertain.

In view of Prof. Birge's letter in *NATURE* of August 1, p. 170, which represents first steps towards the theoretical correlation of the numerous band spectra of carbon, it may not be inappropriate to record a few observations of a purely experimental character with the evidence they afford as to the origin of some of these spectra. During the last couple of years, while working with the inert gases, I have gained a detailed acquaintance with almost all the band spectra of carbon. The various conditions under which it has been found possible to isolate some spectra and eliminate others have inevitably led me to form impressions of their molecular origin.

Without wishing to open the old controversy as to the origin of the Swan bands, the following facts appear significant. The Swan bands can be isolated with exceptional brilliance in 20-50 mm. of any of the inert gases. Of helium, neon, and argon, the last named is perhaps the best in this respect. When a tube is fitted with carbon electrodes, side bulbs containing caustic potash and phosphorus pentoxide, and a palladium regulator, and filled in this way with argon, it usually shows only the Swan bands and the triplet system (*vide* Proc. Roy. Soc., A, vol. 103, p. 390). Prolonged passage of a discharge with the regulator heated so as to remove the hydrogen eliminates the triplet system and leaves the Swan bands, while further running of the tube ultimately removes the latter and there remains only the continuous spectrum of high pressure argon and perhaps the strongest lines of "red" argon. If hydrogen be now admitted through the regulator, the reversed processes can be produced, namely, first the production of the Swan bands with great brilliance, and with much hydrogen, the production of the triplet system. Tentatively, one might suggest a CH or $(CH)_2$ molecule for the former, and a molecule of greater hydrogen content, possibly CH_4 , for the latter.

I am at present engaged in a fine structure analysis of these spectra which will probably yield more definite information of the nature of the radiating molecule. The CH band, $\lambda 4315$, and associated heads can be completely isolated from all other carbon spectra under suitable conditions. In the presence of 20 to 30 mm. of argon or neon containing a little water vapour and a minute trace of a carbon impurity, the system can be produced strongly. What relationship these bands bear to the Swan and triplet systems it is at present premature to say. The fourth positive group is quite possibly of a C-H origin and appears strongly in argon under the conditions of isolation of the triplet system and the Swan bands. It was apparently not observed by M. Baldet in his thermionic bulb when filled with pure carbon-monoxide.

As regards C-O spectra, the recent work of Birge and of Blackburn appears conclusive in assigning the comet-tail bands, the associated bands previously discussed, and the negative carbon bands to a singly charged CO ion. I incline to think from experimental work that the Ångström bands, the third positive bands, and possibly the new band spectrum observed by Cameron (in course of publication) will be found to arise from a neutral CO molecule. As regards the

high pressure CO bands discovered by Fowler, both their complexity of structure and conditions of isolation (which differ so profoundly from those of the comet-tail bands) point to a more complex molecule as the emitter.

The Theory of Hearing.

IN reference to Mr. R. L. Wegel's letter to *NATURE* of September 12, p. 393, under this heading, I think it must be admitted that he and his co-workers at the Bell Telephone Laboratories have contributed a wealth of new facts bearing on the theory of hearing. It will probably be some time before these facts are fully interpreted and correlated, so that their significance in regard to the theory can be rightly appreciated.

Mr. Wegel has elaborated in detail his conception of the deformations of the basilar membrane in response to pure tones of various pitch and intensity. From careful measurements of "masking" of one tone by another, when both tones are sounded together, he estimates the spread of resonant response. The results arrived at are so surprising that the question arises whether the observed facts afford a sufficient basis for the elaborate deductions drawn from them, or whether a simpler solution cannot be found. His primary assumption is that the masking of one tone by another of greater intensity is to be explained by the submergence of the apex of the displacement produced by the masked tone in the basilar membrane by the rising slope of that due to the masking tone (*Physical Review*, February 1924, and Fig. 9, Reprint B. 58. 1).

Mr. Wegel draws the conclusion that the response to a pure tone extends the whole length of the basilar membrane, with a maximum point or apex at a level corresponding to the pitch of the tone. If we take it that the maximum displacement of a stretched string when vibrating freely does not exceed $1/100$ th of the length of the string, it would follow that for a tone of say 800 d.v. per sec. (length of basilar fibre = 0.35 mm.) the displacement of the basilar membrane along its length would have an average slope of about 1 in 5000 on one side of the apex, and 1 in 4000 on the other.

It seems almost incredible that the internal ear could instantaneously detect, and interpret as a single clearly defined pitch, a maximum point of stimulation so slightly accentuated as compared with the displacement of the rest of the membrane. But, one may ask, do Mr. Wegel's curves (Fig. 9, *loc. cit.*) actually represent the deformation to be expected, even granting the spread of resonance which he presupposes? Such a curve should be composite, and should represent the algebraical sum of the components. We should not expect the secondary tone to be entirely masked. It would give rise to a lesser secondary peak. If it caused a displacement of the basilar membrane at all, this should be appreciable, at least as an alteration of the quality of the masking tone. The ear is remarkably sensitive to alterations in the quality of sounds, either musical or unmusical. Its beats with the masking tone, though too rapid to be perceived as beats, would have the effect of doubling its intensity. As it is not perceptible, the inference is that it produces no deformation of the basilar membrane. It is suppressed, not submerged.

The phenomena of "masking" are undoubtedly puzzling, but the outstanding fact that a low tone masks one of higher pitch to a greater extent than a

higher-pitched tone masks a lower one, suggests that the explanation is to be sought in the hydrodynamics of the cochlea. It may be that the larger and slower oscillations of the cochlear fluids associated with vibrations of the basilar membrane in the apical region damp out heterorhythmic vibrations on the proximal side of the membrane over which they pass, and so suppress the higher-pitched tones. It would not follow that the harmonics, which are intermittently homorhythmic, would also be suppressed.

Mr. Wegel finds that subjective harmonics are developed in the case of pure tones of medium intensity. These subjective harmonics apparently do not affect the character of the tone heard. This would suggest that their intensity is not great relatively to that of the fundamental. The ear readily distinguishes between a pure thin tone and a rich full tone in which a number of harmonics are present. If all the "pure" tones we hear contain a whole series of overtones, what distinguishes them from the "rich" tones? That such an extensive "pattern deformation" as is represented in Fig. 1 (NATURE, September 12, p. 393) is generated by each tone which acts on the cochlea is difficult to reconcile with the extraordinary power the ear has of analysing compound musical tones, and even more with its power of instantaneously analysing, and recognising the source of, characteristic noises. This would necessitate an integration of nerve impulses within the auditory tract of almost inconceivable complexity.

Physics and Metaphysics.

It is no doubt a splendid simplification to express the ninety or more chemical elements in terms of two entities, and of only two, namely, electrons and protons, but those who face squarely the problems of physics find it a large leap to follow Mr. Bertrand Russell in "What I Believe," when he states (p. 10): "Physical Science is thus approaching the stage when it will be complete, and therefore uninteresting. Given the laws governing the motions of electrons and protons, the rest is merely geography. . . ."

Those familiar with the life and writings of the late Lord Rayleigh will have come to a directly opposite conclusion, namely, this, that the region to be discovered expands continually with discovery.

The assignment to the world of a wound-up system, like a watch, consisting of protons and electrons, ignores in the first place the problem of radiation, about which we have at present two theories utterly incompatible with one another in the minds of even the finest living intellects.

The further question whether life can be interpreted, for it cannot possibly be explained, by the laws of physics alone is a wide and doubtful issue, on which the best informed are the least emphatic. It is unlikely that any great progress will be accomplished in terms of physics as known or imagined to-day.

Sufficient warning may be found in Kelvin's estimate of the age of the earth, where the logic and mathematics were faultless, so that the conclusions appeared inevitable, until a wholly new branch of physics arose, and radioactivity enabled us to realise that the initial concepts of the problem were founded on insufficient data.

Later in Mr. Russell's book (p. 22) we arrive, however, at the refreshing statements that "the philosophy of nature is one thing and the philosophy of value is another"; and again, "It is we who create value"; and yet again, "In this realm we are kings."

Values cannot be appraised in foot-pounds or calories, nor be cribbed and confined to electrons and protons. Shakespeare and Newton were sustained by food calories as other men are. The foot-pounds or ergs of work expended on "Hamlet" or the "Principia" are comparable in magnitude with those used in the efforts of an ordinary writer or worker. But how can we estimate or express the profound differences in the resulting values! These values are not material, nor can they be reduced to electrons, radiation or æther as understood or imagined by most physicists of to-day.

Another scientific heresy, not imputed to Mr. Russell, but common enough to-day, is the avowal that electrons and protons were "created" in the past, that certain "laws" were imposed upon them, and that the universe has since then been a going concern, running itself from these initial impulses alone. The idea that something created at one instant *must* continue to exist at another instant or for a period of time may be eliminated as a crude conception. The continuation of existence is as difficult to explain as is the initial existence itself.

The only solution that may be offered (and yet it is obviously no solution to us) is that time is the great illusion. We are permitted to see the moving picture film of existence unroll, but the record is, was, and will be always there. Most marvellous of all, we are allowed to take part in the production ourselves, or at least to enjoy the illusion of an active participation therein.

Statements of this kind, passing from the region of physics to metaphysics, are naturally open to more condign criticism than those to which this letter ventures to direct attention.

The Worth of Knowledge.

THE comments on the functions of the British Association, in the article in NATURE of September 12 on "The Worth of Knowledge," raise a consideration that should command the attention of the scientific world, whether interested in the Association or not.

We are justly proud of our science and our scientists. We can point to the departments of science, in our universities and schools, as flourishing institutions, and yet doubt whether they are fulfilling their function to the widest and best extent. Our teachers of chemistry, physics, botany, geology, and all the other branches of science, are men whose names command a world-wide respect. Further, we can agree that the time has passed when any man could include in his survey of life a complete and detailed knowledge of science as a whole. The chemist is to be congratulated if he knows all there is to be known of the chemistry of one small group of substances, and similar conditions hold for other fields of science.

Yet, with equal truth, it may be claimed that science is more than a set of separate departments of natural knowledge; and the claim that the future of humanity rests on a scientific basis can scarcely be denied. This truth and claim are to-day fairly well recognised by a wide public, which is doing its best to get as close acquaintance with scientific work as its non-technical education will permit. As Bateson wrote before the War, "I think it needs little observation of the newer civilisations to foresee that they will apply every scrap of scientific knowledge which can help, or seem to help them in their struggle, and I am good enough Selectionist to know that in that day the fate of the recalcitrant communities is sealed." True in those days, it is urgent and equally true now.

If we have a living faith in the claim, then it is a duty to preach the gospel of science far and wide. I would like to suggest that the time is ripe for the giving of life to that old subject summed up under the term Natural Science. I would like to see a department of natural science as a whole in every university and school in the land, and the growth of the idea that no man—classic, historian, linguist, or chemist—could claim to be educated who had not passed through its curriculum. I am aware that in name such departments do exist, but they cover only a number of specialist courses. The natural science for which I plead should be organised to give wide-flung views of the aims, ideals, and methods of science. They would train the individual to think and act in a scientific manner. The professorial staff should be men who, in the words of your article, could "address a public or any other audience in a manner which will command attention or stimulate interest." The research they would undertake would be the investigation of how best use, not necessarily in the material sense, could be made of scientific advances among the masses of the community.

The matter is urgent, for one has only to read the headlines of a daily paper, watch the hoarding of the kinemas, or the reading matter bought by the general public, to realise that the affairs of the world are receiving "quiet, calm deliberation" very much along Gilbert and Sullivan lines. W. F. F. SHEARCROFT.

The Arc Spectrum of Phosphorus.

KIESS (Jour. Opt. Soc. Am., July 1925) has recently shown that the arc spectrum of nitrogen consists of doublets and quartets, one very particular feature being that the lines lie either in the extreme ultra-violet or in the infra-red. There are some lines in the visible range, but they are excited only under very special circumstances.

The spectrum of the next homologue, viz. phosphorus, has been investigated by Miss Saltmarsh in Prof. A. Fowler's laboratory (*Phil. Mag.* xlvii. 874, 1924). Miss Saltmarsh has shown that the arc spectrum of phosphorus consists of doublets, and has also pointed out certain constant frequency differences.

It appears from an inspection of Miss Saltmarsh's data that the following pairs of lines having the constant frequency difference 250 form a sharp series of the type $2\pi_1$ or $2 - m\sigma$, where $2\pi_1 = 53614.8$ and $2\pi_2 = 53639.8$ approximately.

λ (Å.), Intensity.	ν .	$\Delta\nu$.	m	$m\sigma$.	Difference between Calculated and Observed Values of $m\sigma$.
2536.38 (10)	39426.3	25.4	2	14188.2	+2.8
2534.75 (8)	39451.6				
2154.77 (7)	46408.7	24.5	3	7206.6	+5.3
2153.63 (6)	46433.2				
2034.02 (7)	49163.7	25.2	4	4450.9	+8.0
2032.98 (6)	49188.9				

The more refrangible components of the pairs are fairly well represented by the formula

$$\nu = 53639.8 - \frac{R}{(m + 1.13909 - \frac{0.718054}{m})^2}$$

where $m = 2, 3, 4$ consecutively. Closer agreement

NO. 2919, VOL. 116]

with the observed values of ν and those calculated from the formula is obtained by taking $2\pi_2 = 53645.0$.

The difference between the terms 2σ and $3\sigma = 6982$, and this difference repeats itself in the combination of two pairs of lines having the frequency difference of 14.9 as follows:

	(8)		(6)	
	2136.79		1859.36	
$\pi_1 - 2\sigma$	46799.2	6982.8	53782.0	$\pi_1 - 3\sigma$
	15.0		14.7	
	(6)		(8)	
	2136.10		1858.85	
$\pi_2 - 2\sigma$	46814.2	6982.5	53796.7	$\pi_2 - 3\sigma$

whence $\pi_1 = 60987.4$ and $\pi_2 = 61002.4$.

Miss Saltmarsh has pointed out frequency differences of 7281 and 298, and it is seen here that 7281 is the sum of 6983 and 298, the differences being within the limits of experimental error.

Formation of the Spore Tails in *Haplosporidium chitonis*.

IN *Haplosporidium chitonis* the method of formation of the spore tails, which grow to a great length after the completion of the spore coat, has always been rather difficult to understand; it seemed unlikely that the material for these tails could be provided from the interior of the spore, owing to the thickness of the spore wall, at least toward the end of their growth. On a recent *intra vitam* examination of some of these spores in Janus green, I discovered that, in the younger stages, each is surrounded by a very distinct thick cytoplasmic envelope (Fig. 1, e). The appearance at this stage gives the impression that the spore is being formed inside a cell, but the absence of nucleus outside the spore shows, of course, that this is not the case.

Certain granules can be seen in the envelope, and these appear to be similar to granules inside the spore, which I believe to be mitochondrial in nature (Figs 1

and 2, m). Both sets of granules stain slightly in Janus green. At a later stage, when the spore tails are forming, the cytoplasmic envelope, as such, has disappeared, but it has evidently gone to the formation of the tails, which are now thick and bulging at the proximal end (Fig. 2, e).

Spore formation in this protozoan has been studied by Dr. Pixell Goodrich (*Proc. Zool. Soc. Lond.*, 1915) and Prof. Debaisieux (*La Cellule*, t. xxx., 1920), and by myself in a paper still in press, but the cyto-

plasmic investments of the young spores have not been previously described. The cytoplasm of this form is very delicate, and very susceptible to adverse fixation; this must account for the disappearance of the cytoplasmic envelope in the fixed material from which most of the previous work has been done, as it would have been impossible, otherwise, to overlook such conspicuous structures.

Dispersal of Butterflies and other Insects.

THE letter of Mr. Robert Adkin in the issue of NATURE of September 26, on the vertical upward flight of moths from the Downs near Walmer, supplies one of the desiderata required to confirm the view indicated in Mr. Felt's article in NATURE of September 5 that the upper air-currents may play an important part in the distribution of flying insects. I have myself long expected that the dispersal of insects would ultimately attract the attention of the meteorologist, and Dr. Simpson's British Association address, which immediately precedes Mr. Felt's article, reads appositely beside Mr. Felt's appeal for the aid of convectional currents arising from heated surfaces in assisting insects to gain the upper air-strata. But in this connexion we must not forget that mountaineers have long exercised their brains over the problem of insects on high mountain tops. Whymper in particular, in his work on the equatorial Andes, dealt with this subject, and he quotes Humboldt and Bonpland as showing that insects are transported into the upper regions of the atmosphere (16,000 to 19,000 feet), and adds that the transportation of insects by ascending air-currents has occasionally been observed in operation. One such set of observations is noted by Mr. Felt when he writes, "Collectors on some of the high mountains, such as Mount Washington, have taken insects which are distinctly southern or south-western in habitat, probably carried there by the upper air-currents and dropped upon these cooler mountain tops."

After reading about the recent developments of our knowledge of the upper air-strata, I am inclined more and more to regard the trans-oceanic distribution of insects as carried out mainly in the upper air. My difficulty would be in assuming that insects are hardy enough to withstand the strain of upper-air conditions. When I was camped out on the top of Mauna Loa (13,600 feet) in Hawaii in 1897, this aspect of the question was brought home to me in a striking fashion. The lava rock and beds of cinders outside my tent were strewn with butterfly wings cast off by butterflies which had been brought by the trade-wind current up the mountain slopes from the forests below. The air was intensely dry and extremely electrical, producing distressing physiological effects, which, together with the freezing up of everything liquid in my tent, made life for a man scarcely bearable. To these conditions all the butterflies succumbed that reached the top of Mauna Loa.¹ There their wings lay around me in their hundreds. Mr. Felt should in this experience of mine find the greatest difficulty in accepting the 2000-mile air-trip postulated for Californian insects in reaching the Hawaiian Islands, and perhaps the meteorologist would decline taking on his shoulders the responsibility of Insect Distribution in the upper air.

Mr. Felt suggests the possibility of there being

¹ My observations on Mauna Loa were given in my book on "Plant Dispersal in the Pacific" (1906), and were alluded to in NATURE towards the close of 1897 (vol. 57, p. 20).

sometimes a condensation of insect life at particular levels, due to atmospheric disturbances, and that their instinctive efforts to save themselves may result in the great invasions of insects noticed in different localities. This seems likely enough. Perhaps some air-man on the wing at high altitudes has flown through a bank of insects in the clouds, held there by unfavourable conditions in the air-strata above and below.

Locomotion of the Sunfish.

THE mode of swimming of the sunfish (Mola), which I have had many opportunities of observing at close quarters, is unusual, perhaps unique, but easy to comprehend as compared with that of other fishes. The long dorsal and ventral fins are stiffened on their anterior and flexible on their posterior edges, like the wings of insects. The action of great masses of muscle at their bases causes them to strike the water laterally, first to the right and then to the left, the two fins striking simultaneously towards the same side like wings, but in a horizontal instead of a vertical direction (Fig. 1, B). Owing to the differences

FIG. 1.—A, side view of Mola; B, transverse section in region of fins; C, diagram of Mola seen from above with fins striking to the right.

of flexibility over the surfaces of the fins, their planes are twisted in the act of striking so as to give a forward thrust (Fig. 1, C). Of course, since they strike sideways, there is also a lateral thrust, but this is correlated with the flattened shape of the body, which, acting like the keel of a sailing boat, resists lateral displacement.

The body of the fish is rigid except for the "tail" (*t* in figures), which acts exactly like the rudder of a ship. Fig. 1, C, shows it hard a'port; I have seen it held over like this as the fish turned in a large circle to the right. Since the backwash from the fins does not strike the rudder, one would expect the sunfish to resemble a paddle steamer (as opposed to a screw steamer) in not being able to turn before getting a fair amount of headway on. It is perhaps to provide an auxiliary steering apparatus that the respiratory arrangements are modified so that a very powerful jet of water can be squirted backwards from under either gill cover at will.

The Physiological Basis of Athletic Records.¹

By Prof. A. V. HILL, F.R.S.

FATIGUE AS THE DETERMINING FACTOR.

AN important and interesting problem for any young athlete is presented by the question: "How fast can I run some given distance?" The maximum speed at which a given distance can be covered is known to vary largely with the distance. What are the factors determining the variation of speed with distance? How far, knowing a man's best times at two distances, can one interpolate between them for an intermediate distance, or extrapolate for a distance greater or less?

Obviously the answer to such questions depends upon the factor which in general terms we designate fatigue.

similar factors, which may affect an individual long before his muscular system has given out. Of these three forms of fatigue the first one only is as yet susceptible of exact measurement and description. The second type may quite possibly come within the range of experiment at no distant date. The third type is still so indefinite and complex that one cannot hope at present to define it accurately and to measure it. Undoubtedly, however, all these types of what we call "fatigue" influence—indeed, determine—the results which are to be presented.

In Fig. 1 all the important world's records are pre-

Fig. 1.—World's records for men and women swimming and running: average speed in yards per second against time in seconds. Note.—The scale for swimming is five times as great as for running. The observations for men rowing an eight-oar boat are on the same scale as running and are referred to later in the text.

Fatigue, however, is a very indefinite and inexact expression; it is necessary to define it quantitatively before we can employ it in a quantitative discussion such as this. There are many varieties of fatigue, but of these only a few concern us now. There is that which results in a short time from extremely violent effort: this type is fairly well understood; there is the fatigue, which may be called exhaustion, which overcomes the body when an effort of more moderate intensity is continued for a long time. Both of these may be defined as muscular. Then there is the kind which we may describe as due to wear-and-tear of the body as a whole, to blisters, soreness, stiffness, nervous exhaustion, metabolic changes and disturbances, sleeplessness, and

sented, average speed against time, for men and women running and for men and women swimming. The crosses representing men rowing in an eight-oar boat will be discussed later. It is obvious in all four cases that we are dealing with the same phenomena, a very high speed maintainable for short times, a speed rapidly decreasing as the time is increased and attaining practically a constant value after about 12 minutes. There are no trustworthy records, in the case of swimming, for times of less than about 50 seconds, so that the curves cannot be continued back so far as those for running. There can, however, be no doubt that the curves for running and swimming are essentially similar to one another and must depend upon the same factors. The phenomena shown in Fig 1 are susceptible of a fairly exact discussion.

¹ From the presidential address delivered at Southampton on August 31 before Section I (Physiology) of the British Association.

OXYGEN INTAKE, OXYGEN REQUIREMENT,
AND OXYGEN DEBT.

In recent papers my colleagues and I have tried to emphasise the importance of a clear distinction between the oxygen intake and the oxygen requirement of any given type and speed of muscular effort. When exercise commences, the oxygen intake rises from a low value characteristic of rest to a high value characteristic of the effort undertaken. This rise occupies a period of about 2 minutes; it is nearly complete in 90 seconds. The oxygen used by the body is a measure of the amount of energy expended: one litre of oxygen consumed means about five calories of energy liberated, enough to warm 5 litres of water 1° C.—expressed in mechanical energy, enough to raise about 1 ton 7 feet into the air.

It has been established, however, that the oxygen need not necessarily be used during the exertion itself.

The muscles have a mechanism, depending upon the formation of lactic acid in them, by which a large amount of the oxidation may be put off to a time after the exercise has ended. The recovery process, so called, requires this delayed oxidation: it is just as important to the muscle as recharging to an electrical accumulator. The degree, however, to which the body is able to "run into debt" for oxygen, to carry on not on present but on future supplies, is limited. When an "oxygen debt" of about 15 litres has been incurred the body becomes incapable of further effort: it is completely fatigued. In anything but the shortest races our record-breaking athlete should finish with something near a maximum oxygen debt, otherwise he has not employed all his available power, he has not done himself full justice. The maximum effort, therefore, which he can exert over a given interval depends upon the amount of energy available for him, upon (a) his maximum oxygen intake (that is, his income), and (b) his maximum oxygen debt (that is, the degree to which he is able to overdraw his account). These maxima are fairly well established for the case of athletic men of average size—about 4 litres per minute for the one, about 15 litres or rather more for the other.

It is possible for a man to make an effort far in excess of any contemporary supply of oxygen. This effort will require oxygen afterwards, and the total oxygen needed per minute to maintain the exercise can be measured. It is what we call the "oxygen requirement" characteristic of the effort involved. Now, experiments have shown (see Fig. 2) that the oxygen requirement varies very largely with the speed: it increases far more rapidly than the speed, more like the second, third, or even some higher power of the speed, so that high speeds and intense efforts are very wasteful. These facts enable us approximately to deduce the general form of Fig. 1. . . .

It is obvious, however, that we must not pursue the

argument too far. A man cannot exhaust himself completely in a 100 or a 200 yards race: a quarter-mile, in the case of a first-class sprinter, is enough, or almost enough, to produce complete inability to make any immediate further effort. We have found an oxygen debt of 10 litres even after a quarter-mile in 55 seconds, and one of 15 litres after 300 yards at top speed. It is obvious, therefore, that we cannot pursue our argument below times of about 30 to 40 seconds, and that the maximum speed for very short distances is limited by quite other factors than the amount of energy available. Neither can the argument be applied to very long races, where other types of exhaustion set in.

COMPARISON OF MEN AND WOMEN; SWIMMING
AND RUNNING.

There are certain characteristics of these curves which are of interest. In the first place, those for men and

Fig. 2.—Observations of oxygen requirement of K.F. running and standing-running at various speeds. Horizontally, speed: running, metres per minute; standing-running, steps per minute. Vertically, oxygen requirement per minute, litres.

women are almost precisely similar. For a given time of swimming the maximum speed for a woman appears, throughout the curves, to be almost exactly 84 to 85 per cent. of that for a man. If we assume what is roughly true, that the energy expenditure rises approximately as the square of the speed, we may conclude that a woman swimming is able to exert, per kilogram of body weight, about 72 per cent. of the power expended by a man. Women are well adapted to swimming: their skill in swimming is, presumably just as great as that of men; the difference in the maximum speed for any given time can be a matter only of the amount of power available.

In running, the same type of comparison may be made, and it is found that a woman running is able to liberate in a given time only about 62 per cent. of the energy expendible by a man of the same weight. It is probable that this ratio as determined by swimming and by running respectively is really the same in either case, and that the apparent difference depends upon an inexactness in the simple laws assumed. It would seem fair to take the mean of these two values, 67 per cent., as the ratio of the amount of energy expendible by

a woman in a given time as compared with that by a man of the same weight. It would be of great interest—and quite simple—to test this deduction by direct experiment on women athletes.

THE CHARACTERISTIC OXYGEN-REQUIREMENT-SPEED CURVE AND SKILL.

The curves given in Fig. 2 define the economy with which movements are carried out. By such means can be shown the amount of energy required, in terms of oxygen used, in order, say, to run or swim for a minute at any given speed. The curves will vary largely from one individual to another. It is obvious, however, that such a curve must exist for any person performing any kind of continuous muscular exercise. In it we have a characteristic of that given individual for that particular form of work.

Some people are much more skilled than others. To a large degree, of course, the skill and grace associated with athletic prowess is natural and inborn; to a large degree, however, it can be produced by training and

bicycling. It is obvious at once that neither of these two curves falls anything like so rapidly as does that of a running man; fatigue does not so soon set in; the amount of energy expended at the highest speed must be much less than in a running man. This conclusion, indeed, is obvious to any one who has tried to ride a bicycle fast. It is impossible to exhaust oneself rapidly on a bicycle. The curve for horse-running is almost parallel to that for bicycling; presumably, therefore, the movements of a horse are so arranged that the extreme violence of effort possible in a human "sprinter" is unattainable.

SHORT AND LONG RACES.

Let us pass now to a consideration of the last diagram, Fig. 4. Average speed in a race is plotted against the logarithm of the time occupied in it, the logarithm being employed for the purpose of including all records from 75 yards to 100 miles in the same picture. Fig. 4 presents the data of athletics perhaps more clearly than any other. The initial rise of the

FIG. 3.—Records for horse running and man bicycling; dotted curve for comparison, man running, taken from Fig. 1. Horizontally, time in seconds, vertically, average speed yards per second. Note.—The horse and the man bicycling are shown on half the scale of the man running. The records for bicycling are the unpaced professional records against time. The records for horses were made in America.

breeding. All the movements required in the violent forms of muscular exertion here discussed are rapid ones, far too rapid to be directly and continuously subject to the conscious intelligence: they are largely, indeed mainly, reflex, set going by the will, but maintained by the interplay of proprioceptive nervous system and motor apparatus.

The forms of the characteristic curves of Fig. 2 depend upon the skill of the subject in ordering his movements, just as the "miles per gallon" of the motor-car depends upon the skill of those who designed and adjusted its timing gear and its magneto. Given incorrect adjustment due to lack of skill, given imperfect timing of the several parts of the mechanism, given unnecessary movement and vibration, the whole system will be inefficient. Fundamentally the teaching of athletics for anything but the shortest distances consists in training the performer to lower the level of his characteristic curve, to carry out the same movements at a given speed for a smaller expenditure of energy.

BICYCLING AND HORSE-RUNNING.

Not all forms of muscular exertion are so violent, involve so great an expenditure of energy, when carried out at the highest speed, as running and swimming. In Fig. 3 are two examples of this fact, horse-running and

one mile, and six miles. In Fig. 1 we saw that the speed fell to what seemed to be practically a constant level towards the right of the diagram: this fall represents the initial factor in fatigue. On the logarithmic scale, however, where the longer times are compressed together, the curve continues to fall throughout its length. This later fall is due to factors quite different from those discussed above. Consideration merely of oxygen intake and oxygen debt will not suffice to explain the continued fall of the curve. Actually the curve beyond 10 miles seems to some degree doubtful. Apparently the same extent of effort has not been lavished on the longer records: the greatest athletes have confined themselves to distances not greater than 10 miles. The most probable continuation of the running curve would seem to be somewhere between the lines B and C.

The continued fall in the curve, as the effort is prolonged, is probably due either to the exhaustion of the material of the muscle, or to the incidental disturbances which may make a man stop before his muscular system has reached its limit. A man of average size running in a race must expend about 300 gm. of glycogen per hour; perhaps a half of this may be replaced by its equivalent of fat. After a very few hours, therefore, the whole glycogen supply of his body will be

exhausted. The body, however, does not readily use fat alone as a source of energy: disturbances may arise in the metabolism; it will be necessary to feed a man with carbohydrate as the effort continues. Such feeding will be followed by digestion; disturbances of digestion may occur—other reactions may ensue.

The women's curve, so far as it goes, is very similar to the men's. An enterprising woman athlete who wants to break a record should avoid the 300 metres; she would be well advised to try the 500 metres. It would be very interesting to have an intermediate point between 100 and 220 yards.

ROWING.

There are only a few records available, and those lying between rather narrow limits, for the case of rowing. Taking the case of an eight-oar boat, the most reliable of the data have been plotted in Fig. 1 on the same scale as the running, on five times the scale of the swimming. The observed points, shown by crosses, are somewhat scattered. So far as they go, a mean curve through them would lie practically along the curve for women swimming, but, of course, on five times the scale. The interesting part of the curve to the left

FIG. 4.—Records for men skating, bicycling, running and walking, and for women running. Horizontally, logarithm of time occupied in race, vertically, average speed in yards per second. The same scale is used throughout, except for bicycling, where half the scale is employed, as shown in square brackets. The curve for men running appears to be somewhat doubtful beyond 10 or 15 miles, and three alternative curves are shown by broken lines.

BICYCLING AND WALKING.

As before, the curve for men bicycling, which is drawn on twice the scale vertically of the running curves, is far less steep than they are. The conclusion from this was emphasised above. The walking curve is interesting—it is approximately straight. Physiologically speaking, there is not much interest in the shortest walking races, since here walking is artificial and extremely laborious; running at a considerably higher speed is much more easy. For longer distances, however, say from 10 miles onwards, we have probably in walking the most trustworthy data available for long-continued muscular effort. If we wish to study the exhaustion produced by exercise of long duration, walking-men may well provide the best subjects for our experiments.

is lacking: it is obviously impossible to make observations on an eight-oar boat for periods of 20 seconds; starting inertia is too great and no result of any value could be obtained.

In rowing the movements are slow: in an eight-oar boat, from 30 to 40 strokes per minute. According to observations by Lupton and myself, the maximum efficiency of human muscular movement is obtained at speeds of about one maximal movement per second. In rowing, experience and tradition alike suggest that such a speed is about the optimum. In an eight-oar boat the recovery takes almost as long as the stroke, both occupying about one second. It is of interest how practical experience has gradually evolved a speed of movement which is almost exactly what a physiologist might have predicted as the most efficient. At

a stroke of about 32 per minute the mechanical efficiency is apparently near its maximum.

An enormous amount of work has to be done in propelling a boat at speeds like 10 to 12 miles per hour. According to Henderson, each member of the crew of an eight-oar boat must exert about 0.6 of a horse-power. Clearly, if this enormous amount of external work is to be done, it must be accomplished by working under efficient conditions: those conditions necessitate a stroke of a particular frequency; only when the race is very short is it permissible, in order to obtain a greater output, to work less efficiently by adopting a more rapid stroke. The stroke may rise to 40 per minute for a short distance: in such an effort the oxygen debt is accumulating rapidly and exhaustion will soon set in. The amount of work, moreover, will not be proportionately greater, probably only slightly greater, than at the lower frequency. The conditions which determine the speed of movement, the "viscous-elastic" properties of muscle, are what ultimately decide the length of the oars and the speed of movement in a racing-boat.

WASTEFULNESS OF HIGH SPEEDS.

This last discussion leads us to the question of what determines the great wastefulness of the higher speeds. Why, returning to Fig. 2, does a speed of 280 steps per minute require 24 litres of oxygen per minute, while a speed of 240 steps per minute requires only eight litres of oxygen? The answer depends upon the variation of external work with speed of muscular movement. In a series of recent papers it has been shown that in a maximal muscular movement the external work decreases in a linear manner as the speed of shortening increases. At sufficiently high speeds of shortening no external work at all can be performed.

In most of these athletic exercises, apart from the case of rowing, a large proportion of the mechanical work is used in overcoming the viscous resistance of the muscles themselves. At high speeds of running only a small fraction of the mechanical energy of the muscles is available to propel the body, once the initial inertia has been overcome. The work is absorbed by internal friction, or by those molecular changes which, when the muscle is shortening rapidly, cause its tension to fall off. When working against an external resistance, as in rowing, there is an optimum speed. If an effort is to be long continued it must be made at a speed not far from the optimum. When, however, the whole of the resistance to movement is internal, as in running,

there is no optimum speed: the expense of the movement increases continually as the speed goes up; the faster we move, the greater relatively the price: our footsteps are dogged by the viscous-elastic properties of muscle, which prevent us from moving too fast, which save us from breaking ourselves while we are attempting to break a record.

JUMPING.

One final point may be worthy of mention—this time connected with high-jumping and long-jumping. Recently I made a series of observations, with a stop-watch reading to 0.02 second, of the times occupied by a number of high-jumpers from the moment they left the ground to the moment they reached the ground again. With men jumping about 5 feet the time averaged about 0.80 second. Calculating from the formula

$$S = \frac{1}{2}gt^2,$$

where t is half the total time of flight, the distance through which the centre of gravity of the body was raised must have been about 2.5 feet. The men competing must have had an original height of their centre of gravity of about 2.9 feet. Thus, in the high-jump, their centres of gravity went about 5.4 feet high into the air. The world's record high-jump is 6.61 feet, the centre of gravity of the performer being presumably about 3 feet high at rest. He raises it therefore 3.61 feet into the air, from which we may calculate that the whole time occupied in the jump is about 0.96 second. All the characteristics of the proprioceptive system must be evoked in their highest degree in carrying out such a skilled, rapid, and yet violent movement in so short a time.

In long-jumping, it is well known that success consists in learning to jump high. The world's record long-jump is 25.48 feet. With the check provided by the vertical impulse in the last step we cannot well imagine the horizontal velocity to be greater, at this moment, than that of 100 yards completed in 10 seconds; that is, than 30 feet per second. Let us assume this value, then the performer remains in the air for 0.85 second: hence we may calculate that the vertical distance covered is about 2.9 feet. Assuming the centre of gravity of the subject to have been originally 3 feet high, this means that it must have reached a height 5.9 feet in the air, enough, in a high-jump, to enable its owner to clear 5.9 feet. It is interesting to find that the simple laws of mechanics emphasise so strongly the precepts of the athletic trainer.

A High-frequency Induction Furnace for making Alloys.

A PAPER on a high-frequency induction furnace for making alloys was presented by Mr. D. F. Campbell at the autumn meeting of the Iron and Steel Institute held in Birmingham on September 10. The early work in this field was carried out at Princetown University by Dr. Northrup, whose investigations of the physical laws governing induction from high-frequency equipment led to the evolution of the first metal-melting furnaces. As Mr. Campbell points out, low-frequency induction furnaces have been known for forty years, and twenty years ago it seemed possible that they would, to a large extent, replace the crucible

process for high-grade steel making. This possibility, however, has for a variety of reasons not been fulfilled. Inductive heating has, however, found wide application in the non-ferrous trade in furnaces having a vertical slot worked on normal commercial frequencies. These furnaces have the disadvantage of requiring an iron core, in consequence of which the molten metal is contained in small channels surrounding the iron core as well as in the main bath of the furnace. This involves much wear and tear of the refractory material.

In the case of high-frequency heating the conditions

are quite otherwise. The container is a cylindrical vessel holding the maximum of metal with a minimum of radiating surface and refractory material exposed to corrosive action. The heat is generated in the charge to be melted and consequently there is no loss in the passage through refractory containers as in crucible furnaces. The high-frequency furnace has an immensely steep heat-gradient between the molten metal and the outside of the furnace. The furnace described by Mr. Campbell consists merely of a container or crucible placed inside a flat cylindrical coil. The intermediate space, about one inch in diameter, is filled with zircon or other insulating material contained in a silica or mica sleeve. The crucible need not be more than half an inch thick. As the heat is generated within the metal, the temperature of the crucible is very much lower than that of the metal itself. Consequently, reactions between the metal and crucible walls are reduced to a minimum, and crucibles of material quite inadmissible in other high temperature processes stand up well in the furnace.

According to the author, an ordinary clay crucible, such as is used for gold assays, will make from 10 to 30 heats of nickel-iron alloys containing less than 0.02 per cent. of carbon. A high-frequency furnace mixes the metal very thoroughly. The surface of the molten metal is pronouncedly convex, owing to the violent upward current at the centre of the liquid mass. This is a great advantage for the manufacturer of alloys made from metals which do not mix readily. The frequencies used may be termed "high" or "medium" and have varied from 20,000 to 400 periods per second, the lower figures being applicable to the larger furnaces for melting nickel silver and similar alloys. Furnaces of a capacity of 600 lb. are now working on certain nickel alloys. In cases where it is essential that the alloys should contain a minimum

of carbon, it looks as though they will have a great field of application. The author states that the capital cost of equipment is high, but that some cheapening ought to be obtained in the future.

At present the principal application of this method of heating is in the preparation of alloys which are used for the manufacture of continuously loaded cables. Indeed, the discovery of the two principal alloys now used, namely, permalloy and mumetal, was made possible by the use of a high-frequency furnace. These alloys are composed principally of nickel and iron with small percentages of other metals, and the lowest possible amount of carbon. By the use of this alloy the speed of signalling by long-distance submarine cables has been raised from a maximum of 300 letters per minute for that type of cable to 1800 for a continuously loaded cable. This performance was obtained between the Azores and the United States. An installation recently completed near Birmingham has by far the largest melting capacity of any high-frequency metallurgical works yet erected. The equipment consists of forty-two small converter units of from 35 to 40 kilo-volt ampere capacity fitted with furnaces capable of melting 20 lb of nickel-iron alloys of the highest purity in from 40 to 45 minutes.

Great advantages are also being found for furnaces of this type used in research, owing to the speed with which small heats can be made either *in vacuo* or in air. The author states that in one instance where an investigation was being made into the properties of a series of alloys with a relatively high melting-point, twenty 2-lb. heats were made in eight hours. For some time past the Metallurgical Department of the National Physical Laboratory has included in its equipment a furnace of this type, and great use is being made of it in the preparation of an exceptionally pure series of iron alloys.

Obituary.

PROF. H. H. HILDEBRANDSSON.

THE death of Hugo Hildebrand Hildebrandsson at Upsala on July 29 of this year, at the advanced age of eighty-seven years, marks the passing of a meteorologist of exceptional character. He was secretary of the International Meteorological Committee in succession to R. H. Scott from 1900 until 1907, when he himself retired from the direction of the Institute of the University of Upsala, at which he was the first professor of meteorology, to be succeeded by his son-in-law, F. Åkerblom, the present professor. His name is known throughout the meteorological world for his activity in connexion with the study of clouds in all parts of the world, which culminated in the "International Cloud Year" 1896-97, and found further expression in the "International Cloud Atlas" published mainly under his guidance in 1896, with a new edition in 1910.

Hildebrandsson was scarcely less well known for his researches on "centres of action of the atmosphere" in the Transactions of the Royal Swedish Academy, and still further for his collaboration with Teisserenc de Bort, not only in the investigation of the upper air, but also in the publication through Gauthier-Villars of "Les Bases de la météorologie dynamique: Historique

—État de nos connaissances," a truly magnificent work left unfinished by the untimely death of Teisserenc de Bort. For the text of that work Hildebrandsson was mainly responsible, though it expressed the joint ambition of both to have full regard to the unity of the atmospheric circulation and treat meteorology as a world study. With that ambition, in 1907, the two friends became the bureau of an International Commission for a *réseau mondial*. Teisserenc de Bort wished it to be telegraphic, but the expense at that time being prohibitive, Hildebrandsson pressed the claims of a climatological *réseau*. The Commission still exists, with Dr. Simpson as president, and in the development of wireless telegraphy Teisserenc de Bort's ambition will be realised.

It was in his attitude towards world meteorology and a *réseau mondial* that Hildebrandsson displayed his special characteristic. Most meteorologists are content to write commentaries on some point or subject of physical or geographical importance in the structure or circulation of the atmosphere; Hildebrandsson wanted to make out the connected story of the atmospheric circulation before embarking upon a commentary. He recognised that writing commentaries runs great risk of marking time so long as

the author has only nebulous ideas about the text upon which he comments, and that the elaboration of the text for meteorology is an inductive enterprise of the most embarrassing character. At the same time, he knew that there is no short cut: no ingenuity can produce a substitute for the inductive co-ordination of the real facts of the circulation. Hence the Meteorological Institute at Upsala an academic establishment with no responsibility for any *réseau* of stations, became a centre of illumination and learning for the Scandinavian countries, and typical of a college for the meteorology of the globe, a nucleus round which effective knowledge of meteorology may crystallise with a rapidity as surprising and as beautiful as the laboratory experiment which furnishes the analogy.

Like some other meteorologists, Hildebrandsson began as a physicist and he remained a physicist to the end; but it is clear from the records of his work that he recognised the true basis of the science of meteorology to be neither physics nor geography alone, but a combination of the two

NAPIER SHAW.

MR. THOMAS STEEL.

By the death of Mr Thomas Steel in Sydney on August 17 last, Australia has lost an enthusiastic and observant naturalist. His publications include descriptions of Australian land planarians and notes on their habits. Mr. Steel was born in Glasgow in 1858, and after training as a chemist entered the service of a sugar refinery in Greenock. In 1882 he was appointed chemist to the Colonial Sugar Refining Company of Sydney. Much of his spare time was devoted to the study of the fauna of New South Wales and of Victoria, and he accumulated a large collection of excellently preserved specimens, especially of land planarians and

Peripatus, many of which he gave to the Australian Museum and others to his zoological friends in Great Britain. Mr Steel was a prominent member of the Linnean Society of New South Wales, and was president in the years 1905-7.

PROF S J. JOHNSTON.

PROF S J JOHNSTON has not long survived his former chief, Prof. W. A. Haswell. Johnston joined the staff of the Department of Zoology in the University of Sydney in 1906, and soon became known as a stimulating lecturer and demonstrator in the practical classes. His memoir on the Trematodes of Australian frogs gained for him the doctor's degree in 1912. On the retirement of Prof. Haswell in 1918, Johnston was appointed to succeed him, but his health soon failed and he resigned at the beginning of 1922. He died on July 16.

WE regret to announce the following deaths:

Prof H Bekker, secretary of the Natural History Society (Rerum Naturae Investigatorum Societas), at the University of Tartu (Dorpat) in Estonia.

Dewan Bahadur Lewis Dominic Swamikannu Pillai, president of the Madras Legislative Council, and author of "An Indian Ephemeris, A.D. 700 to A.D. 1799," and other works on Indian calendar systems and chronology, at sixty years of age.

Capt H Riall Sankey, past-president of the Institution of Mechanical Engineers, an authority upon steam and gas engine problems, and consulting engineer of the Marconi Wireless Telegraph Co., Ltd., on October 3, in his seventy-second year.

Sir William Schlich, F.R.S., formerly professor of forestry, University of Oxford, and inspector-general of forests, Government of India, on September 27, at eighty-five years of age.

Current Topics and Events.

CONGRATULATIONS are due to Prof. W. Carmichael M'Intosh, F.R.S., emeritus professor of natural history in the University of St. Andrews, who celebrates his eighty-seventh birthday this week, having been born on October 10, 1838. Time has dealt kindly with this veteran of science, as all must have noticed who, in London, this summer, came in contact with his engaging and breezy personality. A pioneer of research in fishery problems, he was the first to found a marine biological station in Great Britain. Elected a fellow of the Royal Society in 1877, Prof. M'Intosh received a Royal medal in 1899, at the hands of Lord Lister, then president, in recognition of his labours as a zoologist. Earlier (1869) the Royal Society of Edinburgh awarded him its Neill prize for his paper "On the Structure of the British Nemertean, and on some New British Annelids." President of the Section of Biology of the British Association, Aberdeen meeting, 1885, he discoursed at some length on the phosphorescence of marine animals. Last year Prof. M'Intosh received the Linnean medal allotted especially to mark the Linnean Society's admiration for the single-hearted devotion and unremitting industry with which he had engaged in the study of the animal inhabitants of the sea. Oppor-

tunity was taken to congratulate him on the completion of his great "Monograph of the British Marine Annelids," published by the Ray Society. We understand that Prof. M'Intosh has been a fellow of the Linnean Society for sixty-two years, whilst being second in seniority amongst the whole body of fellows, in point of election.

NEITHER students nor staffs have much enthusiasm for the speech-making incidental to the formal occasions of academic bodies, but few of us, happily, are really immune from the infection of ideas, and the flood of formal oratory serves a variety of purposes, mostly good. The London Medical Schools have just experienced such a flood on the opening of their winter session. Prof. Buckmaster, at St. George's, referred to his own student days half a century ago, when the microscope was not of much service to medicine and practically no students possessed one. Some specialists may be found who declare that the days of the microscope are now over, probably a partial and propagandist view. But ten years are enough to cover the latest revolution in medical outlook, for the rise of physiology to its present dominating position is scarcely older. Sir Charles Sherrington, speaking at the London (Royal Free Hospital School),

of Medicine for Women, said the average annual earning of the medical practitioner in England to-day had been put down at between 500l and 600l. The estimate is surprisingly low, and, if trustworthy, should be a salutary reminder that extravagantly paid specialists must constitute but a small group within the profession of medicine. It was not, to his mind, a discouraging average in the era before us, "which must, perforce, be one of national economy and fortitude." Bread alone would not account for the enthusiasm shown in the choice of medicine as a calling. Sir Arthur Keith, addressing the King's College Hospital students, besides suggesting "a curious warfare between the stomach and the brain" (Carlyle, Darwin, Huxley and Spencer constantly complained of their stomachs), repeated a statement which he has made before, much to the pleasure of the lay press, that we do not use all our brains—that "there is no fear of using the matured brain to its fullest capacity." Sir Arthur, always a lively and suggestive speaker, has not, so far as we know, wholly elucidated this thesis. Why should we have inherited for a quarter of a million years, possibly for much longer, an organ of such intricacy if in all the generations of this considerable period we have never used it? Does Sir Arthur Keith mean quite what the newspapers—or even brother anatomists—understand him to mean?

WE have received notice to the effect that the Government of Bombay has been pleased to direct that the Bombay Bacteriological Laboratory at Parel should in future be designated "The Haffkine Institute." The suggestion of change of name appears to have come in the first instance from Lt-Col F. P. Mackie, who received the support of Major-Gen Hooton. The president of the Bombay Medical Council, and the Municipal Commissioner for the city of Bombay, saw no objection to the alteration. The laboratory was first started by Mr Haffkine in 1896 for the preparation of his plague prophylactic and was then housed in Byculla. Later (1899) it was moved to the present site and was called the Plague Research Laboratory and afterwards was named "The Bombay Bacteriological Laboratory." Since 1896, more than 25 million doses of plague vaccine have been issued from this institute, and it is considered just that Haffkine's name should be attached to the Laboratory on the analogy of the Lister or Pasteur Institutes. There must, however, be many who would not assign to W. M. Haffkine a place beside Lister and Pasteur. Waldemar Mordecai Wolff Haffkine comes of a Jewish family and was born in Odessa in 1860. He was educated in Odessa as a geologist, and after a short time with Schiff the physiologist in Geneva, migrated to Metchnikoff's department in the Pasteur Institute in Paris. Here he held a subordinate post and developed his ideas on cholera protection by inoculation. Through the influence of Lord Dufferin, especially, he went to India in 1893 and inoculated a large number of people against cholera and at a later period against plague. He was a man of uncanny enthusiasm and was

regarded by many as a prophet of a new regime. Thirty years' persistence of plague in India have not entirely established his fame as a great reformer.

IN the October issue of the *Forum* Dr E. E. Free discusses what he regards as "one of the most surprising failures of modern chemistry"—the failure to create life. For Dr Free the problem is really that of the origin of protoplasm, and he tries to reconstruct the environment in which its abiogenetic synthesis may have become possible. It is refreshing to find an American rejecting the Planetesimal Hypothesis in favour of the more recent views of Jeans. Few of the British school, however, will agree that after the earth had solidified, the sun's heat was still sufficient to maintain the surface at a temperature of 1,400° F. At a later stage during the cooling of the primeval atmosphere Dr. Free supposes that prussic acid and carbon monoxide were formed, followed by water, and he thinks it reasonable to assume that in the resulting ocean a natural synthesis of glycocoll and other amino-acids occurred. These had millions of years to be built up into more complex compounds, and at last the remarkable reaction was achieved whereby something akin to protoplasm came into being and started off the course of evolution that has culminated in man. The earliest known relics of life seem to represent bacteria, and on the other hand, glycocoll has already been prepared in the laboratory. The suggestion is that the gap is narrowing, and that chemists may soon succeed in synthesising "protoplasm." But it may well be doubted whether the chemist who first makes "protoplasm" will, as Dr Free appears to hope, have also created life. A piece of protoplasm cut from an *amaba* soon dies if it does not contain the nucleus, and it is surely unreasonable to anticipate that the chemist's "protoplasm" would fare so much better that it could reverse the process and come to life where no life had been before.

DR. ALEŠ HRDLÍČKA, whose lecture at the Royal Anthropological Institute on his recent visit for purposes of archaeological investigation to India, Java, Australia, and South Africa appears in another column, is universally recognised as one of the foremost of American anthropologists. For many years he has been Curator of Physical Anthropology in the United States National Museum at Washington. His first contribution to anthropological literature was made in 1895, when he published a report on an investigation of the characters of the inmates of an institution for juvenile delinquents, in which he was able to show that the theories of Lombroso on signs of degeneracy to be observed in the physical characters of the criminal had no basis of fact. Dr Hrdlička is perhaps best known for his work on the question of the antiquity of man in America. He has studied carefully all the osteological remains from that continent to which high antiquity has been attributed, and has visited the sites on which they were found. As a result of these investigations he was forced to the conclusion that neither in North nor in South America was there any evidence which

supported anything but a relatively recent date for the peopling of the continent. It has been an inestimable gain to archaeological studies that the first trained observer to visit the Broken Hill Cave and investigate the conditions of the discovery should be so stern a critic of evidence as Dr. Hrdlička.

IN a recent article (*NATURE*, August 22, pp. 265-267) on modern developments in British optical instruments, reference was made to the acknowledged superiority of British photographic lenses over those of foreign manufacture. It is satisfactory to learn from the makers of such lenses that the importation of optical glass for the manufacture of photographic lenses of the best type is now almost negligible. Before the War, the optical glass supplied by the one British manufacturer engaged on its production excelled that from abroad, kind for kind, both in transparency and homogeneity—the two essential properties, but only twenty-six types were available. These did not afford sufficient variety to meet the needs of the lens makers, who were thus dependent upon Germany, and to a less extent upon France, for their supplies of special glasses. The production of new types of glass was systematically developed in Britain during the War; and two additional firms took up its manufacture. There are thus three home sources of supply. The oldest of these firms now lists eighty optical glasses, and the quality of its products has been maintained. British photographic lens makers are now reaping the benefit of the enterprise shown by the glass manufacturers. The experience gained by the latter, combined with the research facilities now available, should assist them in supplying the optician with such new types of glass as may be called for as the result of developments taking place in optical science.

WE note with pleasure that work has been recommenced on the Exhibition Road frontage of the new buildings of the Science Museum, South Kensington. These buildings, planned some thirteen years ago, were supposed to have been completed in 1915, but while the skeleton ferro-concrete structure was being erected the War broke out, and the galleries were made later habitable for war-time offices by filling in the walls with temporary brickwork. This brickwork is now being demolished. It is thought the galleries will be completed in about two years and then the Museum will be in possession of suitable entrances, a feature it has always lacked. For years visitors have had to proceed by the rather disreputable passage at the side which suggests to one the entrance to a slum rather than a great national museum. We still think the Office of Works might make it less forbidding though it has to do duty for only two years longer.

ON September 30, in the Usher Hall, Edinburgh, before an audience of nearly three thousand people, Capt. Roald Amundsen was presented with the Livingstone Gold Medal of the Royal Scottish Geographical Society in recognition of his polar achievements. The Rt. Hon. Lord Salvesen, president of

the Society, in presenting the medal said that it was offered as a token of the admiration that Edinburgh people had for the gallantry, courage and endurance which Capt. Amundsen had displayed in the various arduous undertakings which he had initiated. The Livingstone Gold Medal was endowed to the Royal Scottish Geographical Society in 1901 by Mrs. A. L. Bruce in memory of her father, Dr. David Livingstone, to be awarded for distinguished services to geographical exploration or research. This special honour has been conferred on fifteen previous occasions, the recipients being Sir Harry H. Johnston, Dr. Sven Hedin, Commr. R. E. Peary, Capt. R. F. Scott, Sir Archibald Geikie, Sir George D. Taubman Goldie, Viscount Milner, Lord Avebury, Sir Ernest Shackleton, Sir John Murray, Capt. Evans, Lord Kitchener, Mr. Douglas W. Freshfield, Col. Frederick M. Bailey and Dr. Marion I. Newbigin.

As a sequel to the work of the Australian National Research Council in securing the foundation of a chair of anthropology in the University of Sydney, the Rockefeller Foundation is sending a delegation to Australia in November to visit the various universities and study at first hand their work and plans for research in anthropology and in all those sciences which may be grouped under the heading of "human biology." The delegation will consist of Mr. Edwin R. Embree, director of the Division of Studies of the Foundation, and Dr. Clark Wissler, head of the Department of Anthropology of the American Museum of Natural History.

IN the budget presented to the Commonwealth Parliament on August 14, provision is made for the appropriation of the sum of 100,000*l* for the purposes of the Commonwealth Institute of Science and Industry. This represents a very large increase in the annual income of this Institute, which will shortly be completely reorganised and put in a position to attack national scientific problems in a manner hitherto beyond its resources. Proposals for a new constitution have been prepared at the request of the Commonwealth Government by a conference representative of the chief industrial concerns and scientific organisations of Australia, but it is not yet known to what extent they will be accepted by the Cabinet and submitted to Parliament.

THE Russian Academy of Sciences has received information of the discovery of an ore containing a valuable radioactive uranic mineral. The ore was found by Labuntsov on the western coast of the White Sea in the course of investigations on some mica and feldspar quarries on behalf of the Mineralogical Museum. It is expected that further deposits of this ore will be revealed in those regions. Deposits of this nature were unknown in Russia before. Hitherto this ore was found chiefly in the Congo. Samples of the new mineral were on view at the Mineralogical Museum during the recent bicentenary celebration of the Academy of Sciences.

THE third International Limnological Congress was held at Moscow in the "Home of Science" on August

25-30. The opening of the Congress was preceded by a visit to Leningrad, where a public reception in honour of the foreign delegates was given by the Russian Geographical Society. The delegates then visited the Hydrological Institute, the Zoological Museum of the Academy of Sciences, the Botanic Gardens, and the Scientific Research Institute at Peterhof. At the close of the session the delegates left for Saratov to inspect the oldest biological station, whence they travelled down the Volga to the Caspian Sea, inspecting the Volga and Caspian fisheries.

A NOTE from Carl Meissner, now Curator of the Botanic Gardens at the University of Kowno, Lithuania, but formerly Curator of the Botanic Gardens, Leningrad, which appears in the *Gardeners' Chronicle* for August 8 last, throws a vivid light upon the difficulties under which plants have been reared at the Botanic Gardens, Leningrad, during and since the War. With improvised incubators or other heating arrangements, however, Meissner still succeeded in raising *Victoria regia* and sends an interesting photograph to the *Gardeners' Chronicle* which shows one of the floating leaves of this enormous aquatic plant supporting the weight of a full-grown woman (72 kilograms). The appearance of the leaf margin shows that this unusual weight is causing considerable distortion of the leaf, but it is a striking example of the great buoyancy and strength of this floating lamina.

THE Georgian Academy of Sciences (Tiflis) had recently organised an expedition to study the architectural monuments scattered in different parts of the country. The main objects of interest were found at Uplisziche, Samzevrisi and Svimosti. Uplisziche is a cave city hewn out in the rocky banks of the river Kura, near Gori. It is one of the most ancient architectural monuments in Georgia, part of the caves being traceable to the epoch of the Roman Empire, the majority, however, belonging to the Middle Ages. Samzevrisi and Zromi are represented by monuments of ecclesiastical architecture of the pre-Arabic period, while at Svimosti there is a basilica belonging to the eleventh century.

WE learn with regret that the Comptroller of the British Patent Office has been prevented by indisposition from attending the international conference on industrial property, which is being held at the Hague. His absence will mean a serious loss to the British delegation, for Mr. Temple Franks has earned a high reputation as an exponent of British patent law. At the last moment, however, Mr. H. A. Gill, president of the Chartered Institute of Patent Agents, was appointed to take his place, so that the delegation will not lack an experienced technical expert. The appointment of Mr. Gill was a wise step, particularly in view of the fact that, for some unexplained reason, no representative of the technical staff of the Patent Office is accompanying the delegation.

A SPECIAL exhibition of palæolithic implements recently discovered by Dr. O. Hauser in excavations in Saxony has been arranged in the Naturkundliches Heimat-Museum, Leipzig, and will remain on view until the end of November.

A PUBLIC inaugural lecture on "Science and Culture" will be delivered on Friday, November 6, at 5.30 P.M., at King's College, London, by Prof. Julian S. Huxley, who was recently appointed to the chair of zoology in the college, in succession to the late Prof. A. Dendy.

THE Chemical Engineering Group of the Society of Chemical Industry performs two useful functions, one of which is educational and the other commercial. Many of the papers read before it contain useful information which is not otherwise easily obtainable in a compact form; other papers serve mainly to direct attention to special types of plant which are, or may be, on the market. Volumes 5 and 6 of the Group's Proceedings, covering the years 1923 and 1924, have recently been issued under one cover; they contain thirteen contributions together with reports of the supplementary discussions. As types of the purely educational paper may be mentioned those by Mr. B. Heastie on heat-transmission and on water-purification; genuine research work is represented by a valuable paper on silica gel as an adsorbent, by Prof. E. C. Williams, of University College, London; and descriptions of manufacturing plant and processes are embodied in papers on the manufacture of wood-extract, water-softening, the extraction of oil from seeds, nuts, and kernels, centrifugal dryers and separators, the Premier and other disintegrating mills. Prof. J. W. Hinchley contributes an interesting paper on the large-scale manufacture of potash fertiliser, alum, etc., from Italian leucite, and Prof. F. G. Donnan gives some useful control formulæ for leaching and evaporating, with special reference to the Chilean nitrate industry. Several of the papers were communicated to joint meetings of the Group and other societies, and in many instances the discussions were informative.

A BIBLIOGRAPHY of meteorological literature prepared by the Royal Meteorological Society, with the collaboration of the Meteorological Office, has recently been issued by the Royal Meteorological Society. At first the bibliography formed part of the Society's Quarterly Journal, but since 1920 it has been published in six-monthly parts. References are added to the several papers to indicate where they are located. The divisions deal with general meteorology, methods of observation and computation, instruments, physics of the atmosphere, investigations of the upper atmosphere, the several elements of meteorology such as temperature and rainfall, climatology, and terrestrial magnetism. The publication is of value to meteorologists in different parts of the world. The price to non-fellows is 2s. 6d.

THE British Museum (Natural History) has recently issued Series 7 and 8 of postcards in colour illustrating flowering plants native to Britain. Each series of five cards (price 1s.) contains a brief discussion of the elements of the British flora, together with a list of the plants in the series, each with brief descriptions. The general account concludes as follows, after referring to some of the rarer elements in the British flora. "Rare

plants should not be picked except for special reasons, they should be investigated and left to seed. Wild-flower competitions in which children are told that they must actually pick a flower before they add it to their list are much to be deprecated."

We have received from the firm of Eisenschmidt, 60 Dorotheenstrasse, Berlin, a complete catalogue of German official maps, including the maps published by the various States and the geological maps. There is added a catalogue of Austrian maps. Full indexes of most of the issues are given with the catalogue.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned. A poultry instructor at the Norfolk Agricultural Station, Norwich—The Director of the Station, 11 Bridewell Alley, Norwich (October 17). Junior assistants at the National Physical Laboratory in the electricity and aeronautics departments—The Director, National Physical Laboratory, Teddington (October 24). Two research fellows in the department of Glass Technology of the University of Sheffield—The Registrar (October 24). An assistant for soil survey work in the Harper

Adams Agricultural College, Newport, Salop—The Principal (October 26). A professor of surgery in the University of Lucknow—The Registrar (October 31). A senior lecturer in botany and agronomy, and a lecturer in geography (especially in human and commercial geography), in the Transvaal University College—The Registrar, Transvaal University College, Pretoria (November 12). A professor of physics in the University College, Colombo, Ceylon—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W. 1 (November 20). An assistant lecturer in agriculture at the Harper Adams Agricultural College, Newport, Salop—The Principal. A senior hydraulic engineer by the Government of the Gold Coast—The Crown Agents for the Colonies, 4 Millbank, S.W. 1 (quoting M/13968). A computer for the Gold Coast Survey Department—The Crown Agents for the Colonies, 4 Millbank, S.W. 1 (quoting M/13965). Teachers for evening classes at the Northampton Polytechnic Institute in the subjects of mathematics, electricity, mechanics and heat, light and lens workshop—The Principal. A fellowship in chemistry at Trinity College, Dublin—The Registrar.

Our Astronomical Column.

MEASUREMENT OF PLANETARY RADIATION.—W. W. Coblentz and C. O. Lampland describe their researches in this field in *Lowell Observatory Bulletin*, No. 85. Various screens (fluorite, quartz, water, glass) were used to isolate different regions of the spectrum, bismuth and platinum-rhodium wires were chiefly used in the thermo-couples, tellurium wire is found to be still more sensitive, but its action is slower.

The percentage of radiation that is planetary (i.e. due to warming of the planet's surface or atmosphere) is 3 from Jupiter, 9 from Venus, 15 from Saturn, 30 from Mars, 80 from the moon. It thus increases with diminution of atmospheric density. It cannot be inferred, where the atmosphere is dense, that the surface of the planet is as cold as these figures would indicate. It is, for example, quite improbable that the surface of Venus (on the sunlit side) is near freezing-point; the measures really refer to a high layer in its atmosphere. The case of Mars is discussed in great detail. It is concluded that its day surface temperature may reach 10° or 20° C, while that of the moon may reach 80° or 100°.

Investigations on stellar temperatures were also made. The results range from 13,000° for ϵ Orionis, B α , to 3000° for Antares, M α , and β Pegasi, M β .

A NEW THEORY OF VARIABLE STARS.—Dr J. H. Jeans contributes a paper to the June issue of the *Monthly Notices of the Royal Astronomical Society* that contains some bold speculations connecting the long-period variable stars with spectroscopic binaries. He collects statistics of these binaries from *Lick Observatory Bulletin* 385, and deduces the mean value of the sum of masses of the two components as 18 (Sun), and the mass ratio as 0.73, the less massive star having the "earlier" spectral type. His suggestion is that the long-period variables represent the stage preceding fission in such stars. He postulates that both rotation and oscillation are present, and that the periods of these are at first different but gradually approach each other, becoming identical just before fission. The theory is shown to account

for several observed types of light curve, including the Cepheid type. Since even the M type variables have frequently a single definite period of light change, it is thought that these stars may have commenced the fission process in an earlier non-luminous stage. The author concludes that the temperature of both stars rises at fission, and thus explains the prevalence of type B in spectroscopic binaries.

SPIRAL NEBULÆ.—Dr K. Lundmark, who has for some years made a special study of these objects, has written a further paper on them in the *Monthly Notices of the Royal Astronomical Society*, 85, No. 8. He first discusses proper motions and radial velocities, the latter are concluded to reach a maximum of 2250 km./sec. at a distance of 110 Andromeda-nebula units, or 10⁶ light years. The sun is moving (relatively to the spirals) towards galactic longitude 75°. It is conjectured that this may arise from a rotation of our local stellar system in a period of 3.10⁸ years. The proper motions appear to be too small and doubtful for use. From the fact that they appear to be less than 0.01" annually, a minimum distance of 30,000 light years is found. Indirect methods give much greater distances. Assuming the novæ in spirals to be of the same character as galactic novæ, distances of the order of a million light years are found for the nearer spirals, in good agreement with Dr Hubble's results from Cepheid variables found in them. In this case the bright Nova S. Andromedæ, found in 1885, was of absolute magnitude -16, and was comparable with Tycho's Cassiopeia Nova. Dr Lundmark has found a star of magnitude 13.7 and spectral type M β , which is probably Tycho's star. Its spectrum shows giant characteristics, and it is concluded to have been of absolute magnitude -16 at maximum.

The paper concludes with some interesting speculations on the Lambert-Charlier suggestion of successively higher orders of systems, galaxies of galaxies, and so on. The facts, so far as known, are concluded to accord with the suggestion.

Research Items.

EXORCISM IN ZANZIBAR.—Mr W. H. Ingrams describes in the September number of *Man* certain customs observed by the inhabitants of the village of Makunduchi, Zanzibar, which are not found elsewhere among the natives of the island. The inhabitants of this village and the adjacent village of Jembiyani speak a peculiar and distinctive dialect, although both belong to the Wahadimu, the aboriginal inhabitants of the island. One characteristic feature of their culture is an exorcising dance performed by the women, the orchestra only consisting of men. The women possessed of the devil sit in a small tent while the dancers move backward and forward from sunlight to shade under a palm-leaf shelter. Some of the women carry iron tridents on long handles, others knives and swords, and others model outrigger canoes and paddles. As the devil cannot speak the local dialect, a special incomprehensible jargon is used. The devil can only be contracted at sea, and a legend of the origin of this state of possession has it that the devil first appeared from the sea in a canoe and holding a trident. It is suggested that the rite and legend may enshrine a memory of a cult of Poseidon introduced by early Greek sailors who, it is known, travelled along East Africa, and to whom the first description of Pemba and Rhapta is due. It is noted that a coin of Ptolemy X Soter has been discovered at Msasani, north of Dar-es-Salaam.

MAGIC AND MEDICINE AMONG THE AMERICAN INDIANS.—Mr. Charles Whitehead, of the U.S. National Museum, in Art. 10 of vol. 67 of the Proceedings of the Museum, gives an account of the Indian exhibits in the collections which illustrate the history of medicine. The Indians attributed disease to the operations of spirits, or it might be caused by absence of the patient's soul. Consequently the remedial measures were almost entirely magical, and even in the therapeutic use of plants, more importance was attached to their magical properties, the incantations with which they were gathered and the ceremonial accompanying their use, than to experience of their healing properties. In fact, their use was usually determined by some imagined resemblance or relation to the symptoms of the disease, or its mythical cause. Disease was closely connected in their myths with animals, especially the deer. Consequently, for a disease caused by the rabbit, the antidote must be a plant called the rabbit's foot, rabbit's ear, or rabbit's tail; for snake diseases the plant used is snake's tooth; for worms, a plant resembling a worm, and so forth. Their knowledge of surgery was based on a comparative knowledge of the anatomy of the higher animals. Splints, bandages, and the cautery were used, and bone-sets, cupping by sucking, poulticing, cutting, counter-irritation, and venesection were practised. For the last, small chips and flakes of flint were employed as lancets.

TYPES OF AVALANCHES.—In an article on "Les Catastrophes de la Neige" in *Matériaux pour l'étude des calamités*, No. 5, 1925, M. A. Allix suggests a classification of avalanches based first on the condition of the snow, and secondly on the effects of the avalanches. He recognises avalanches of dry snow, occurring below freezing point, and of wet snow, with a higher temperature. These produce respectively cold and warm avalanches, the terms being used relatively. Cold avalanches occur as streams of fine powdered snow following the snowfall. When once a crust has formed on the fallen snow it moves in slabs or flakes (*plaques*) to which different names are given.

Warm avalanches of wet snow occur in larger slabs of relatively slow movement, of which several forms are recognised. All avalanches have a common origin in loss of equilibrium. If the snow is in a state of unstable equilibrium, the most insignificant cause may start the avalanche. A fall of rock, the movement of a train in the valley, even the sound of a voice may furnish the secondary cause. Other causes also operate: unequal contraction due to rise and fall of temperature; saturation of snow with water; and lack of initial cohesion. The paper considers protective measures and includes a short bibliography of the subject.

THE MANURING OF FRUIT TREES.—In the *Journal of Pomology and Horticultural Science*, vol. IV Nos 3 and 4, June 1925, Mr T. Wallace makes perfectly clear the need for more scientific experiments upon the manuring of fruit trees, and commences the description of a series of manual experiments he has carried out at the University of Bristol Agricultural and Horticultural Research Station, Long Ashton, in which fruit trees, bush and smaller fruit, have been grown in sand culture in pots and supplied with mineral salts in solutions of known composition. These experiments should ultimately provide data of great interest to the plant physiologist, carried on as they have to be over long periods of time. In the present paper, the results obtained with apple trees, in experiments lasting over four years, are briefly given. In order to aid diagnosis of possible causes of trouble when the expert is called in to report upon lack of progress in fruit trees grown commercially, Mr. Wallace has adopted the plan of comparing the growth made by trees receiving all necessary nutrient elements with that made by trees in which one essential element alone is lacking. In four years, cultures along this line have yielded many results of great interest. For example, the large leaf growth and relatively good root growth obtained in cultures lacking calcium or magnesium compares strikingly with the poor root formation when potash is deficient, when the leaves also show great tendency to scorch and to fall early. Nitrate or phosphate deficiency is associated with late and weak development of both leaf and flower bud. Characteristic tints also appeared in the foliage before falling in many cases; thus magnesium deficiency was associated with purple blotches in the relatively large leaves before they fell. Such distinctions suggest that Mr Wallace's hope to obtain information of value for diagnosis, if applied cautiously to meet the problems arising in practice, is in a fair way to be fulfilled.

RAINFALL IN KOREA.—The Meteorological Observatory of Zinsen (known more familiarly to the western world as Chemulpo) has published a volume of remarkably complete statistics on the "Rainfall in Chôsen (Korea)." The text is entirely in Japanese, but the tables, which form the bulk of the work, have also English headings, and being accompanied by a series of excellent maps, ignorance of the language is no bar to extracting any information which may be desired. Although Korea was probably the first country in the world in which rainfall observations were taken at a network of stations (a number of rain-gauges were in use so early as A.D. 1442), modern meteorology is of very recent development, and in a country of the size of Britain there are records for only 215 stations, most of which were established less than ten years ago. Apparently no attempt has been made to correct these various short series to a common period, and the maps must be regarded as provisional.

only Nevertheless they give us our first clear idea of the distribution of rainfall in Korea. The annual amounts are similar to those in Britain, ranging from 18 to 68 inches, but the falls come chiefly in the summer monsoon in very heavy showers. Ten inches in a day have been recorded at many stations, and the maximum of 19.42 inches (485.5 mm.) in a day at Kosyu greatly exceeds anything known in Britain. The tables also include heavy falls in successive days, greatest and least monthly totals, number of days with various totals, and greatest falls in eight hours and in one hour. The latter table is based on self-recording gauges at eight stations.

THE ACOUSTICS OF HALLS.—The ease and certainty of the methods worked out by Sabine for the testing and improving of the acoustic properties of lecture halls are well illustrated by an article by Mr. A. G. Coombs in the September issue of the *School Science Review*. The new school hall at Berkhamstead was notoriously bad, the audience being unable to distinguish the words in the confused sounds that reached them. On shouting in the empty hall the reverberation continued for 10 seconds, and calculation of the time from the dimensions by Sabine's method gave 13 seconds. By covering the back wall and the ceiling under the gallery with 1800 square feet of "Cabot" quilting made of fireproof eel-grass, and the floor of the gallery with 850 square feet of cocoanut matting, the time of reverberation of the empty hall was reduced to 3 seconds, and of the hall and audience to 1.5 seconds, and it is now possible to hear in it without strain. The author has found the oboe suitable for producing the sound of constant loudness necessary for the tests.

BULLET PHOTOGRAPHY.—Although there is a general impression that the study of ballistics has made great advances since the War, it is only occasionally that an article dealing with such advances is published. The Bureau of Standards at Washington has designed an apparatus for bullet photography for the Frankford Arsenal, and Scientific Paper No. 508, by Mr. Philip P. Quayle, Assistant Physicist to the Bureau, gives an account of the apparatus and some of the interesting results obtained by its means. The spark is derived from a Leyden jar charged by an electrical machine and passes on the closing of a trigger spark gap by an electromagnet operated, without interfering with the bullet, either by the firing mechanism or by the passage of the head wave of the bullet over an interrupter. By means of the apparatus it has been shown that the service projectile from a 0.30 Springfield rifle ceases to be accelerated within a foot of the muzzle. Thirty-six figures are given, most of them photographs of the bullet with the head and sound waves, and several of them relate to the effects produced by the passage of the bullet through a soap bubble containing hydrogen (*v. also NATURE*, May 16, p. 765).

ROTATION OF THE PLANE OF POLARISATION OF ELECTROMAGNETIC WAVES.—Experiments with a molecular model consisting of four metal balls fastened together by wooden rods so as to form an irregular tetrahedron, which showed that in certain positions the plane of polarisation of an electromagnetic wave was rotated by this molecular model, have previously been described by Dr. Karl F. Lindman; and in the *Annalen der Physik* for August he describes a series of observations in which a considerable number of similar models with the balls embedded in spheres of paraffin wax were prepared, and placed in veneer or cardboard boxes which were put in the path of the waves. As many as eighty-five such molecular models were packed irregularly into a

single box, and it was shown that their action on the waves was that of a practically isotropic substance, the rotation of the plane of polarisation depending only on the thickness of the layer of models through which the wave passed, and not on the orientation of the box, the amount of the rotation being proportional to the thickness. The direction of the rotation depended on the form of the asymmetrical molecular models. Observations were made with waves of different frequencies, and it was found that the relation between the rotation of the plane of polarisation, the wave-length employed and the wave-length of the natural vibrations of the models agreed with the formula deduced from Drude's electrodynamical theory.

STEEL MOULDING SANDS.—The steel castings industry of Great Britain is notoriously inferior to the best continental practice, particularly German and Belgian. One reason for this is that insufficient attention is paid to moulding sands and their properties. A very comprehensive paper on "Steel Moulding Sands and their Behaviour under High Temperatures," presented at the recent meeting of the Iron and Steel Institute by Mr. A. L. Curtis, does something to remedy this defect. Mr. Curtis has shown that great variation occurs in natural argillaceous sands of Pliocene origin, of which the St Erth variety may be taken as representative, and that similar variation occurs in steel facing mixtures in current practice. It may be concluded, therefore, that much more frequent control tests are necessary before either choosing supplies of raw sands or preparing facing mixtures in the steel foundry. Mr. Curtis has developed certain tests, *e.g.* refractory and washing tests, which are more rapid than chemical analysis, and suggests that control tests could be rapidly made by these methods. He also describes permeability and dry crushing tests which afford a sufficient indication of the physical qualities of any resultant facing mixture. The factor of mechanical "green" strength has an important bearing on steel facing mixtures. Mr. Curtis indicates that results of his tests on these lines are in progress. The paper is fully illustrated with figures and photomicrographs. It should prove very useful to the industry.

MALLEABLE AND NON-MALLEABLE NICKEL.—For more than one hundred years after its application, nickel found very little industrial application. This was partly because the metal itself was not widely known and partly because as ordinarily produced it was non-malleable. In 1879 Fleitmann discovered a process for producing malleable nickel on a commercial scale, which consisted simply in adding about 0.1 per cent. of metallic magnesium to the molten metal just before casting. This process has been very successful, and is the method used to-day in the production of malleable nickel castings, and of ingot metal to be worked into sheet, rods, wires, and tubes. It has generally been supposed that it was the presence of oxygen which rendered the nickel non-malleable, and that magnesium acted as a deoxidiser. Recent work by Merica and Waltenberg has shown that this is not the case. Reference is made to this work in the *Metallurgist* of August 28. These authors conclude that neither oxygen, carbon, silicon, arsenic, iron, copper, cobalt, nor manganese impair the malleability of nickel. The harmful element according to them is sulphur, the presence of which, in amounts exceeding 0.005 per cent., is sufficient to cause lack of malleability in furnace-refined nickel. Magnesium as a desulphuriser is remarkably efficacious in removing the sulphide Ni_3S_2 , which is present as a eutectic, and surrounds the nickel crystals with a film which renders them brittle.

Dr. Hrdlička on Early Man.

AT a special meeting of the Royal Anthropological Institute held on September 29, when Sir Arthur Keith, ex-president, was in the chair, Dr. Aleš Hrdlička, of the Smithsonian Institution, Washington, gave an account of his recent journey to India, Java, Australia, and South Africa for the purpose of visiting the sites upon which discoveries relating to early man had been made, and exhibited bones and other relics from the cave at Broken Hill in which the skull of Rhodesian Man was discovered. These remains are to be deposited at the British Museum (Natural History) at South Kensington. Dr. Hrdlička said that on his arrival in India he was surprised to find that, in addition to the new species of fossil apes from the Siwalik Hills already known, two or three more new species had been discovered and were in the Calcutta Museum, but had never been described. Their discovery had been made by Dr. Pilgrim, superintendent of the Geological Survey, and there was a risk that these important investigations in the Siwalik Hills, where fossil remains abounded, might not be continued. In Java he had visited the site on which *Pithecanthropus erectus* had been discovered. Here again there was a great field for discovery, but priceless material which might bear upon the history of man was being lost for ever as it washed out of the deposits and was thrown away or destroyed by the natives. From Australia, perhaps, a great deal was not to be expected. The Talgai Skull was so nearly akin to those primitive specimens, the Australian skulls, that it may not be very ancient; but definite conclusions are not yet possible.

In South Africa, within the last four years, two discoveries of the greatest importance had been made—Rhodesian Man and the Taungs Skull. On the position of research in South Africa, Dr. Hrdlička had a great deal to report and a great deal that was favourable. In the matter of the finds themselves, some very important details were not yet known and had not been mentioned. Broken Hill itself, the kopje in which Rhodesian Man had been found, had now disappeared, owing to mining operations, but nearby was a similar hill, which, like Broken Hill, was honey-combed with fissures and caves in which it was hoped that further discoveries might be made. Dr. Hrdlička then described the mining operations which, in digging out the material of the hill from the top, had cut across a section of the cave. In clearing out this cave, which was full of refuse highly consolidated, it had been found that the upper and nearly level part before the steeper slope began, was nearly choked

with animal bones, which have now been smelted down. Here and there were softer spots from which the material had been thrown out into dumps. In the lower part of the cave were deposits which were nearly pure lead and of the consistency and colour of brown sugar. Near the cul-de-sac in which the cave ended, a miner named Zwiegler, working with a native boy, had brought to light the Rhodesian Skull resting on its base on a shelf as if placed there. No bones of any kind were near it. Under the skull was something which was described as a bag of "petrified" skin. This had now disappeared. From 3 to 6 feet further in had been found a human tibia, and still further a skull of a lion. Dr. Hrdlička had himself worked over the dumps which still remained and had found a stone implement, possibly part of a knife, a stone ball similar to some found before in the cave, a number of animal bones, some of which had been split as if to extract the marrow, and part of a humerus. Both the humerus and the femur, of which fragments were found, had been fractured in the same way and as if for the same purpose as the animal bones. The fracture of the humerus was undoubtedly ancient, and cannibalism would be no matter for surprise.

The discovery of the Taungs Skull, like that of Rhodesian Man, was wholly unlooked for in this part of Africa. It was an anthropoid of a new type, and it came from a site that was only partly exhausted. From pockets of soft pink limestone due to the filling in of caves which had formed in a hard ferruginous limestone plateau, large numbers of skulls of baboons were to be, and had been, obtained, and also in some cases where the skulls had perished, brain casts had been obtained. Dr. Hrdlička himself had found five skulls, of which he had succeeded in extracting three unbroken. These baboons had apparently crawled into the caves and fissures to die and had then been covered up by the deposit. Among these the Taungs Skull, the skull of a young anthropoid of a new species, had been discovered. It had been cleared of the deposit in a month's careful labour by Prof. Dart, and it was a tribute to his skill that the skull had not suffered a scratch in the course of the process. Arrangements had been made for a careful watch to be kept for any further discoveries and for Prof. Dart to be summoned at once should anything be found, so that it might be seen by him *in situ*. This skull was not the "missing link," but only one of many missing links, but in view of these remarkable finds, it was impossible to say what South Africa might not produce in the future.

Library and Information Service.

THE second annual conference of the Association of Special Libraries and Information Bureaux was held at Balliol College, Oxford, on September 25-28. Nearly two hundred delegates attended, which was more than double the number present at the first meeting. The diversity of interests attracted to the conference was surprising; scientific and research institutions, industry and commerce, and public affairs all being strongly represented. The marked variety of the professions of those attending caused widespread comment as to the real source of interest which was taken in the proceedings. A heavy, almost overloaded, programme of papers, numbering more than thirty, fully occupied the conference during the whole of the session.

Undoubtedly, the common link is the collection and the distribution of fact information. Special

organisations for assembling and systematically storing literature in limited fields of knowledge, and still more those for distributing information therefrom, for the service of their members or others, are found to be much more numerous than was previously recognised. The Association has done much good by demonstrating this, and is now engaged in pursuing some obvious developments which arise from the discovery. Most of these organisations are quite distinct from ordinary libraries, in fact, in some cases their own collections may be limited to indexes, or other aids to rapid contact with scattered outside library resources.

One of the first objects in view is the preparation of a "Directory of Special Libraries and Information Bureaux" in Great Britain, for which the support of the Carnegie United Kingdom Trust has been

obtained. This directory is intended to place on record the existence of all these bodies, and by suitable annotation to show clearly the field covered by the individual organisations and their facilities for a thorough command of their territory, even when their services are limited to the private needs of their members.

Another almost equally important object is the encouragement of an improved supply and a better distribution of scientific and other periodical literature, the vast extent of which has only just been clearly demonstrated by the publication of the *World List of Scientific Periodicals*, which will be referred to later.

The support of the movement for co-operation, nationally and internationally, in improving the service of abstracts in different branches of science, was discussed at the conference; and although there is no intention of such a youthful organisation venturing to interfere with matters which obviously belong to older and more specialised institutions, it is clear that a body of this sort provides a useful forum for diffusing knowledge of the results of experience in different branches of science.

The international outlook of the conference was demonstrated by the presence of M. Otlet, of the *Institut International de Bibliographie*, Brussels, and visitors from Germany, Holland, and the United States. The goodwill and friendly interest from the United States, where a *Special Libraries Association* has been in existence for sixteen years, was demonstrated by the reception of a presentation set of their journal and other tokens.

Sir Arthur Steel-Maitland, Minister of Labour, welcomed the delegates in an opening speech, and strongly urged the national importance of the work of the Association to enable Great Britain to maintain its position in the industrial field. He feared that both the U.S.A. and Germany were more diligent than was Great Britain in keeping track of the results of pure and applied research, and in providing the means for their record and diffusion.

Prof. Gilbert Murray dealt with the work of the *Intellectual Co-operation Committee of the League of Nations*, in a contribution of particular value, since so little is known in Great Britain of this branch of the League of Nations. Foremost in its activities was the support of bibliographical enterprise, and only the lack of funds limited the extension of this work, which was considered so important for reconstruction. "It is by reading one another's books that we get into one another's minds. It is by co-operation in scientific and philosophical research, it is by co-operation in building up literature and art of the countries that we can hope to get the minds of the different nations moving again in concord, and working towards something like a common end."

Dr. Chalmers Mitchell spoke of the "*World List of Scientific Periodicals*," which has just been published with the help of the British Museum authorities, and which discloses the existence of nearly 25,000 separate periodicals issued between 1900 and 1920. He explained fully his suggestion for a central library to contain a complete file of all periodicals publishing scientific research, the library to be kept available for abstractors and indexers, and to retain the periodicals for at least two years after publication. This library would be in no sense a rival to existing libraries, which would continue to form the permanent home of their own collections. In the past, many institutions had been proud of their possession of a few hundred or a thousand periodicals, the "*World List*" should encourage a wider view of the situation, and stimulate

co-operation and a pooling of resources so as to render available a better aggregate provision of literature for the scientific worker.

Sir Horace Plunkett described the *Co-operative Reference Library*, which it is hoped to transfer from Dublin to London. The conference passed a special resolution welcoming this proposal, as it was thought likely to be of great assistance in developing the agricultural progress of the country.

Miss A. L. Lawrence, of the *British Medical Association*, provided an interesting review of the "*Co-ordination of Medical Information*," describing work in the U.S.A., France and this country, which was usefully supplemented by Dr. O. Kentish Wright, with an account of the service of the Ministry of Health.

Mr. Langdon-Davies (*Labour Publishing Co., Ltd.*) explained that the relatively small editions of scientific books were not necessarily a drawback if some clearer forecast of the demand could be arrived at. In another direction, he hoped libraries and publishers would not overlook the extraordinary thirst for knowledge of the manual workers, and the resulting need of clear and simple exposition of scientific and literary subjects.

Engineering science was fully represented by papers from Brig.-General Mowat, with an account of the library of the *Institution of Mechanical Engineers*, and Major Simnett on engineering and transport intelligence.

The conference greatly appreciated the opportunity of hearing from Dr. A. E. Cowley, Bodley's Librarian, something of the work of that great institution, the Bodleian, which is more and more tending to departmentalise its collection to meet the growing specialisation of knowledge.

The session on Sunday morning was devoted to a series of papers by leading representatives of the library service of the three main political groups. The description of their organisation and work showed that a high standard of intelligence service is aimed at, going far beyond any narrow party need of the moment. The information sections of such government departments as the Board of Education, Ministry of Health, and Imperial Institute were described, and certainly widened the knowledge of most of those present as to sources available in this direction.

The field of general library administration is fully covered by the chartered "*Library Association*," and the friendly relations between this older body and the present gathering were demonstrated by the presence of several members of the Council of the Library Association, who contributed papers and took part in the discussions. An attempt is to be made to explore the possibility of closer relations between the two bodies, but it is clear that they function to a large extent in different directions, and the newer body mobilises, probably for the first time, the interests of library users.

Perhaps of even more importance than the formal discussions was the opportunity which the conference afforded for personal intercourse between specialists engaged in such diverse callings. Without the conference many of these might never have come in contact with one another for the discussions of the few, but important, matters which their professional interests have in common.

The immediate future task of the Association, the preparation of a *Directory of Special Libraries*, can be materially assisted by the goodwill and support of scientific bodies in response to a questionnaire which will shortly be issued by the organising secretary, Mr. G. W. Keeling, from the Association's office at 38 Bloomsbury Square, London, W.C.1. R. S. H.

University and Educational Intelligence.

ABERDEEN.—Dr. Alexander Low, reader in embryology at the university, has been appointed to the chair of anatomy, vacant through the resignation of Prof. R. W. Reid.

NEWCASTLE.—At the meeting of the council of Armstrong College held on October 5, Dr. Frank Smith was appointed professor of education in succession to Prof. Godfrey H. Thomson, who has been appointed to Edinburgh. Since 1914, Dr. Smith has been Senior Lecturer in Education and Master of Method at University College, Aberystwyth.

THE following lecture arrangements of the Royal College of Physicians of London have been made: The Bradshaw lecture will be given on November 5 by Dr. E. Bramwell, who will speak on "The Myopathies"; the FitzPatrick lectures, on "Medicine in Ancient Egypt, Assyria and Palestine," will be given on November 10 and 12 by Dr. A. Shadwell; the Lloyd-Roberts lecture will be given by Sir Arthur Keith on November 16 (the subject will be "Man's Structural Defects"). The Bradshaw and FitzPatrick lectures will be given at the College at 5 o'clock, and the Lloyd-Roberts lecture at the Royal Society of Medicine at 5.30.

FROM the Technological Institute, Cawnpore, we have received a prospectus which describes the arrangements made for putting into operation the scheme adopted by the Government of the United Provinces in 1921 for combining instruction in chemical technology with research in industrial chemistry. Three courses are offered, each of three years' duration, namely, in general applied chemistry, in oil extraction and refining, and in leather manufacture. The classes are limited to three students in each department in each year of the course, and only graduates in science are admitted. Arrangements have been made enabling students to receive practical training in oil mills in Cawnpore, Bombay, and Ahmedabad, and in the Government Harness and Saddlery Factory, Cawnpore.

ADULT education in some shape or form should be regarded by the whole community as a benefit in which every one of its members should participate as a matter of course. This is the ideal, proposed by the Master of Balliol at the annual conference, held at Oxford last month, of the British Institute of Adult Education—"a real students' university for adult education." Some account of the London County Council's efforts in this direction is given in "A Guide to Continued Education in London," a new edition of which has just been issued. In this particulars are given not only of classes in commercial and technical industrial subjects, art schools, and day continuation schools, but also of various kinds of "institutes," literary, women's, men's, and free, in which instruction of a more or less informal character is given. All of these are of recent origin, the latest being the junior men's institutes of which five have been opened experimentally for the season 1925-26. They are open daily from Monday to Friday from 7 to 10 P.M., and the subjects of instruction include "English in the form of topics of interest to boys, wood and metal work, 'hobbies,' gymnastics, and boxing." Every endeavour is being made to introduce the "club" atmosphere and influence so as to attract boys for whom the more formal instruction given at the ordinary commercial institute has no appeal.

Early Science at Oxford.

October 14, 1684. A letter from Dr. Turberville contained severall observations relating chiefly to ye eyes; and, which is yet more oblidging, it contained also his promise to communicate to us more observations of ye same kind. The Society then ordered, that their thanks be sent to ye Doctor, for what he has already imparted, and for ye hopes he gives us of a continued correspondence with him.

A discourse concerning Sands and Clays, and another discourse concerning the quicksilver in barometers, both written by Dr. Lister, were read.

Dr. Plot comunicated an abstract of a letter, sent him by Dr. Tyson, which is as follows: I have lately sent me, by Caspar Bartholin, a small tract he has put out *de ductu salivæ, hactenus non descripto*.—An Acquaintance of mine has lately put forth a Chronological Map from ye Creation to this time, in 16 large sheets of paper; which may either be pasted together in one or two maps, or else contrived conveniently into a booke.

He also communicated a substance, called *Solda*, which came from Timoa, one of ye Moluccas; it looked like an elmbark, had an aromatic smell, is an excellent Osteocolla, when pounded to powder, and put into spirits of wine.

He shewed us also a peice of silver talc, from Norway, on which fire makes no impression; and informed us, that in Staffordshire there are mountains of gold talc, which yeld not to violent fire.

The same Person shewed us a peice of copper, from ye East Indies; it was very heavy, of an irregular figure, like ye top of a cone, but flat; in which figure that mettall naturally grows in ye mines, whence this pattern was dug.

October 20, 1685. The Minutes of ye Dublin Society from July 6, to August 12 1685 were read, and ye thanks of ye Society ordered for them; there being mention made in them of wanting Insects according to ye matter of their ffollicles, thus method was supposed by Sr. Richard Bulkly then present at ye meeting to be impracticable, forasmuch as Insects of ye same species make use of materials of severall sorts, some of which are used by Insects of other kinds.

The same Gentleman was pleased to entertain ye Society with a farther account of his Calesh, which, he saies, is not onely uneasie, but dangerous for two persons to ride in at ye same time; but one person can travaile in it with greater ease to ye horse, than if he were on ye horse's back.

He gave ye Society an account of his Anemoscope, and presented them with draughts of a monstrous Child lately seen at Dublin.

There being some discourse concerning ye effect bleeding has on ye Eye-sight, arguments were urged from experience both for its being injurious, and its being advantageous to ye sight: Bleeding in fulnesse of vessels has cleared ye sight for some time, but frequently administered, and in a weak constitution, has taken from the strength of ye sight.

A letter from Dr. Vincent of Clare-Hall, Cambridge, concerning Dr. Papin's water engine, a letter from Mr. Over, Physitian at Winchester, to Mr. Coward of Merton College containing two cases of persons in ye small-pox, and a letter from Mr. Derham to Dr. Bathurst concerning some anatomical observations in dissecting a child, were all communicated and read.

October 21, 1684. A letter of Mr. Lewenhoeck's, being observations about the Chrystalline humors of ye eye &c, was read.

On October 21, 1684, mentioned frequently in ye Minutes of the Society, a great deal of rain, observed, and a hard frost.

The Effect of Diuresis on Purin Metabolism.—E. J. Channon and Prof. J. C. Drummond. Feeding Experiments with Spinnecens.

Mining Institute of Scotland (at Edinburgh).

MONDAY, OCTOBER 12.

ROYAL SOCIETY OF MEDICINE (War Section), at 5.—Lieut.-General Sir William Leishman: Presidential Address.

INSTITUTE OF MECHANICAL ENGINEERS (Graduates Section), at 7.—G. Lyon: An Analysis of Tests on a High-speed Petrol Engine.

INSTITUTE OF METALS (Scottish Local Section) (at 39 Elmbank Crescent, Glasgow), at 7.30.—J. Stirling: Chairman's Address.

INSTITUTE OF BREWING (London Section) (at Engineers' Club, Coventry Street, W.),—Discussion on this Season's Malta.

TUESDAY, OCTOBER 13.

PREHISTORIC SOCIETY OF EAST ANGLIA (at 52 Upper Bedford Place, W.C.), at 2.30.—M. C. Burkitt: Some Aspects of the Azilian-Tardenoisian Industries (Presidential Address).

INSTITUTE OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 8.30.—E. Parsons: Notes on the Geology of Java.

INSTITUTE OF MARINE ENGINEERS, at 8.30.—W. S. Patton: Corrosion.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (at 11 Chandos Street, W.), at 8.30.—Sir Percy Z. Cox: Mesopotamian

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—R. A. Hudson: Town Planning: its Effect and Influence on Industry.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—Dr. G. H. Rodman: The Story of Cuckoo Spit.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—F. Turville-Petre and Sir Arthur Keith: Early Man in Palestine: the Galilean Skull.

WEDNESDAY, OCTOBER 14.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. S. L. Cummins: The Prevention and Arrest of Tuberculosis.

INSTITUTE OF CIVIL ENGINEERS (jointly with Institution of Mechanical Engineers, Institution of Electrical Engineers, Institution of Naval Architects, Institute of Marine Engineers, North-East Coast Institution of Engineers and Shipbuilders, Institution of Engineers and Shipbuilders in Scotland, Institute of Chemistry of Great Britain and Ireland, Institution of Gas Engineers, British Electrical and Allied Manufacturers' Association, British Engineers' Association, Admiralty, War Office, and the Air Ministry), at 6.—R. A. Chattock: Standard Codes for Tabulating the Results of Trials on Steam Turbines and Condensing Plant.

INSTITUTE OF ENGINEERS-IN-CHARGE (at St. Bride Institute, Bride Lane, E.C.), at 7.30.—Eng. Vice-Admiral Sir George G. Goodwin: Presidential Address.

INSTITUTE OF CHEMICAL ENGINEERS (at Science Museum, South Kensington), at 8.30 (Reception).

THURSDAY, OCTOBER 15.

ROYAL AERONAUTICAL SOCIETY (at 7 Albemarle Street), at 8.30.—Major C. K. Cochran-Patrick: Aircraft Survey in Burma.

INSTITUTE OF MINING AND METALLURGY (at Geological Society of London), at 8.30.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss Margaret Macmillan: The Future of the Nursery School.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—Prof. C. V. Raman and Suvil Krishna Datta: On Brewster's Bands. Part I.—W. G. Collins: Demonstration of a New Method of Recording Rapidly Varying Phenomena.

CHEMICAL SOCIETY, at 8.—Prof. H. B. Baker and Miss M. Carlton: The Effect of Ultra-violet Light on Dried Hydrogen and Oxygen.—Miss M. Carlton. A New Peroxide of Barium.—U. R. Evans. The Production of Oxide Films on Copper at Ordinary Temperatures.—Mrs. A. H. Atack and F. W. Atack: The Structural Isomerism of the Oximes. Part III. The Benzilmonoximes.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.), at 8.15.—Dr. A. Balfour: Some of Our Pioneers (Inaugural Address).

FRIDAY, OCTOBER 16.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Specimens illustrating the Pathological Anatomy of Aconegaly.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. W. Bennett: Ely Cathedral (Lecture).

INSTITUTE OF METALS (Swansea Local Section) (at University College, Swansea), at 7.15.—Captain H. Vivian: Chairman's Address.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. J. Tracey: Super-Tension Cable Dielectrics.

INSTITUTE OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 8.—J. L. Adam: The Engineer and his Ship.

SATURDAY, OCTOBER 17.

PHYSIOLOGICAL SOCIETY (at Guy's Hospital).

PUBLIC LECTURES.

SATURDAY, OCTOBER 10.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: The Earliest Egyptians and their Remains.

MONDAY, OCTOBER 12.

UNIVERSITY COLLEGE, at 5.—R. J. Lythgoe: The Physiology of Hearing and Vision (Succeeding Lectures on October 14, 15, 21, 22, 23, November 2 and 4).—Prof. G. Dawes Hicks: The Philosophy of Bradley and James Ward.

KING'S COLLEGE, at 8.30.—Rev. Dr. F. A. P. Aveling: Applications of Psychology.

MEDICAL SOCIETY OF LONDON, at 8.30.—Dr. L. S. Burrell: Tuberculosis from the Physician's Viewpoint.

TUESDAY, OCTOBER 13.

BEDFORD COLLEGE FOR WOMEN, at 12 noon.—Miss Tarrant: Greek Philosophy.

UNIVERSITY COLLEGE, at 8.—Prof. E. A. Gardner: Proposals for Restoration and Excavation in Athens.

GREENHALL COLLEGE, at 6.—Sir R. Armstrong-Jones: Physics (Succeeding Lectures on October 14, 15, and 16.)

WEDNESDAY, OCTOBER 14.

LONDON SCHOOL OF ECONOMICS, at 5.—Prof. L. Rodwell Jones: Geography and the University.

UNIVERSITY COLLEGE, at 8.30.—Dr. E. A. Baker: The Use of Libraries.

THURSDAY, OCTOBER 15.

UNIVERSITY OF LEEDS, at 5.15.—A. M. Woodward: The Excavation of Sparta.

KING'S COLLEGE, at 8.30.—Prof. C. Burt: The Contributions of Psychology to Social Hygiene.

Co-ordination* of Food Research.¹

THE appointment of the Imperial Economic Committee was a further step in the evolution of the Empire, and, should it be successful, an important one, for the aim is to promote "the greater prosperity of the Overseas Empire, the better distribution of the white population within the British Commonwealth, and the better employment of the population which remains at home." This the Committee hopes to accomplish by devising "methods of turning the trend of commerce into channels which will most effectively assist in the development of the Empire"; and it goes on to say that this "is a task at once complex, difficult and delicate, and [one which] cannot be hurried"—a conclusion with which few will disagree.

This first report before us confines itself to food, and the daily press has familiarised the public with the main feature of the proposals put forward, namely, the establishment of a permanent organisation, modelled broadly on the lines of the Development Commission, designed to secure regularity and continuity of supplies, and to conduct a publicity campaign "calculated to appeal particularly to the young, so that a habit [of consuming Imperial products] may be engendered in the coming generation." It is obvious that the effects of such a campaign could not be wholly commercial. If it were successful, it must increase the sense of empire, and of imperial responsibilities in the people. Its political import, therefore, would be great.

The special interest of the report to readers of NATURE lies in Part II., which is headed "The Importance of Research." "We are impressed," says the Committee, "by the paramount importance of research in solving the problems of the food supplies of the Empire," and to meet this need it proposes what is neither more nor less than the establishment of an imperial scientific service with headquarters and institutions in every geographical unit. A beginning has already been made towards such a state scientific service. At home there is the Department of Scientific and Industrial Research; in Canada and Australia there are parallel organisations; whilst at the Cape there is an active scientific division of the Department of Mines. Co-operation already exists, but it is almost exclusively of the kind which commonly takes place in the scientific world—interchange of papers and letters, and, much more rarely, of actual workers. The Committee aims at something more, namely, the co-ordination of these several and scattered organisations into a real imperial scientific service for the application of science to the food industries. This it hopes to

¹ Report of the Imperial Economic Committee on Marketing and Preparing for Market of Foodstuffs produced in the Overseas Parts of the Empire. Pp. 38. Cmd. 2493. (London: H.M. Stationery Office, 1925.) 9d. net.

attain by strengthening the scientific organisations in each country, and by establishing a system of studentships and grants which shall make it easy for scientific workers within the service to move from one part of the Empire to another.

Ultimately, the Committee hopes to see developed "an organised profession, trained at the Universities, specialised at the Research Stations, practised in research on a commercial scale, and utilised and rewarded in the trade at large," and "a professional institution which would play the same part in the food industry as that played by the Institution of Civil Engineers and the Institution of Mechanical Engineers in their industries."

That there is room for some such development as the Committee has outlined is not open to doubt. The application of science to the handling of food is patchy. On the engineering side it is good—cold storage engineering, for example, is as completely scientific as any other branch of engineering. But on the biological side, the industry, broadly speaking, is unscientific, and there is a great field for the application of botanical physiology, of biochemistry, and particularly of colloidal chemistry, to the problems of the storage of flesh, fruit, and vegetables. The food industry needs not only laboratory work on the biological side, but also infiltration by men with some training in the biological sciences—all this the Committee recognises. Before these aims can be attained, however, much persistent advocacy will be necessary. It is greatly to be hoped, therefore, that strong endeavours will be made to press forward the recommendation of the Committee as to research, until the scheme suggested is put into practice.

The Fundamentalist Controversy in the United States.

- (1) *Both Sides of Evolution: a Debate.* By the Rev. Charles Spurgeon Knight. Pp. 233. (San Jose, Cal.: The Arthur H. Field Publishing House, 1925.) 1 dollar.
- (2) *The Dogma of Evolution.* By Prof. Louis Trenchard More. (Louis Clark Vanuxem Foundation Lectures delivered at Princeton University, January 1925.) Pp. vi + 387. (Princeton: Princeton University Press; London: Oxford University Press, 1925.) 16s. net.

THE nature of the fundamentalist controversy in the United States, and the issues that are really at stake in it, are admirably illustrated by these two books, which we propose to review together. The first is an account of a public debate which is stated to have taken place in some small town disguised under

the initial N—in what Americans are prone to call "the wild and woolly west"; the other is a series of lectures admirably thought out and expressed, delivered before an academic audience in Princeton in the cultured east. In the first book, it would be difficult to assign the palm for crudity of thought and expression between the supporters and opponents of evolution; but the second book is a mine of valuable facts and of thoughtful criticism, though, like the first, it contains a polemic against the theory of evolution in its ordinary American presentation.

(1) If we turn to consider the first book more in detail, we find that it consists of an introductory address on the history of the theory of evolution by the president of the State University, followed by a defence of evolution by Prof. Allen, the local biologist. This is succeeded by an attack on evolution and a defence of the doctrine of special creation by Dr. Barkly, who is apparently an eminent Californian divine. A rejoinder by Prof. Allen then follows, and the book concludes with a second attack by Dr. Barkly. As the author of the book is the Rev. Dr. Knight, who describes himself as pastor and evangelist, it is not surprising that he considers the supporters of evolution to have been finally vanquished, and that he is careful to let the Church speak last. From the preface we might be disposed to infer that the president, Prof. Allen, and Dr. Barkly are imaginary characters, and that the whole of the arguments are the outcome of Dr. Knight's brain, and for the credit of our biological confrères in California we hope that this is indeed the case.

We note to begin with that the word "Evolution" is understood in its widest Spencerian sense: it is defined as including the nebular theory of Laplace and the supposititious development of living from non-living matter. It is evident from "Dr. Barkly's" rejoinders that what is chiefly attacked by the fundamentalists is this speculative extension of the theory of evolution, and we consider that the whole case for the validity of the theory of organic evolution is prejudiced by binding it up with such wild and baseless guesses as that for which the authority of Dr. Salesby (*sic*, ? Saleeby) is quoted to the effect that the ferments constitute the bridge between living and non-living substance, or that of Prof. Leonard Trolland, of Harvard, who states that life is an "autocatalytic reaction." If science be defined as the study of natural processes and the imaginary prolongation of them into the past and future, then no conclusion is more firmly based than that life only arises from pre-existing life, and that therefore in all sound theories of organic evolution the fundamental properties of living things must be taken for granted and are the postulate on

which all our reasoning is founded. If we make guesses as to the spontaneous generation of life from dead material, we are stepping outside science, and invoking what may be called an extra-natural or supernatural agency; and there science, which deals with processes and not with origins, comes to an end.

The supporters of evolution lay stress on the wonders alleged to have been performed by Dr. Burbank in producing new varieties of plants by crossing. These wonders, which have been "featured" in many popular western accounts of evolution, have evaporated under detailed criticism, and it is due to Dr. Burbank himself to say that he has never countenanced the extravagant claims which some of his admirers have made on his behalf. For the rest, the well-known arguments from embryology (including the tailed stage in the development of man), from palæontology, from comparative anatomy, and from the peculiarities of island species are somewhat vividly presented. We may note in passing, as an example of intense provincialism, the astounding statement that Prof. A. Franklin Shull had "demonstrated the descent of the elephant from the *Mœritherium* of the upper Eocene" (*sic*). That this demonstration was effected by our own beloved and deeply regretted Dr. Andrews, of the British Museum (Natural History), is overlooked entirely.

The attackers of the theory of evolution are, of course, quick to seize the opening provided for them by the inclusion of superannuated theories of cosmogony and guesses as to the origin of life within the ambit of the evolution hypothesis. That theories of cosmogony are in the melting-pot, it is easy, in these days of Einstein and of radioactivity, to demonstrate. Indeed, if "Dr. Barkly's" attention had been directed to some recent utterances by the talented secretary of the Royal Society, he would no doubt have felt his position strengthened. In the columns of *NATURE*, Dr. Jeans has discussed the number and variety of atoms which were originally "created." Dr. Barkly stresses the point to which we have alluded above, namely, that life is never generated from dead matter, but he goes on to say: "It should be remembered that spontaneous generation is a necessary part of evolution as held by most evolutionists. If this fails part of the foundation on which they erect their theory is shattered beyond repair."

When he comes to the field of organic evolution, most of Dr. Barkly's arguments are incredibly crude; but there are one or two of them that are worthy of attention. His trump-card is Mendelism, and he quotes Dr. Batson (*sic*): "That particular and essential bit of the theory of evolution which is concerned with the origin of species remains utterly

mysterious; we no longer feel as we used to do that the process of variation now contemporaneously occurring is the beginning of a work which needs only time for its completion, for even time cannot complete that which is not yet begun." There are many of us who fully agree with Dr. Bateson that the mutations with which Mendelians experiment have played no part in the evolutionary process; but so far from the genesis of species being mysterious, we hold that it is as clear as daylight to those who look in the right direction for a solution, and that nothing but the obstinacy of the Mendelians in persisting in searching in the wrong direction is the cause of the mystery which they find therein. When we discover that every wide-ranging species is split into local races, that a new local race establishes itself every time a new territory is colonised, that contiguous local races are fully fertile, *inter se*, but that distant races begin to show the mutual infertility which is characteristic of distinct species, we feel that the problem is in a fair way to its final solution.

Another argument of Dr. Barkly's is that domesticated animals and cultivated plants tend to revert to the wild type when neglected, and that therefore these breeds are not analogous to wild species. This, we think, is a valid argument. The diagnostic features of species are all reactions to their environment—in a word, adaptations to it—but the peculiarities of domestic animals, however useful to man, however "developed" from his point of view, are mere monstrosities from the point of view of the animals themselves, and owe their origin to disturbances of the developmental processes which result from the unhealthy conditions to which the germ is exposed at a critical period of its growth. As a consequence, we have "germ weakness" which is transmitted from generation to generation and produces similar results in each. But this germ weakness gradually disappears when normal conditions are restored; and so the domesticated pigs released in Jamaica in the seventeenth century have reverted to a form almost identical with the wild boar. It is, we hold, the one regrettable but natural mistake in the "*Origin of Species*" that Darwin considered these domesticated breeds as examples of the process which gave rise to new species.

It would be pointless and would weary readers of *NATURE* were we to recount Dr. Barkly's other arguments, such as: "If eyes were developed from pigment spots why are they not being developed now?" or "If this going backward from a hoofed animal down to a fish is not the opposite of all evolution, then the development of a horse out of a fish cannot be evolution at all, which, of course, overthrows the whole Darwinian theory at a blow."

Dr. Barkly's final reply is a pæan in praise of what religious teaching and religious belief have done in building up and upholding American civilisation. With much of what he says, all must agree; and it is the subconscious feeling that the American presentation of the theory of evolution threatens to undo the work of religion, which, as we have already pointed out in a previous communication to *NATURE*, is the driving force behind the fundamentalist movement. But though we have no desire to discuss religious questions in these columns, we cannot forbear to give one choice example of the crudity of Dr. Barkly's ideas: "Children always inherit through their parents—Jesus inherited through His mother for He was every whit a man, and He would have inherited through Joseph if Joseph had been His father, but in that case He could never have been more than a man. . . . The miraculous in His life is the manifestation of His Divine heredity." Comment is superfluous!

(2) It is a relief to turn from such outbursts of half-educated ignorance and prejudice to the calm scholarly and scientific atmosphere of Prof. More's book. In the series of lectures embodied in it he begins by emphasising the complete break between modern and medieval modes of thought which, according to him, began at the Renaissance. The first sign of the break began with the heliocentric system of Copernicus, but the Church did not realise the implications of this system until it was openly promulgated by Galileo, whose trial brought the conflict between the old and the new to a head; but, as Prof. More remarks, it is not true that opposition to science, whenever it has showed itself, is directed against the physical sciences themselves. Public opinion, according to him, is always indifferent to scientific theories, interest in which and eventual hostility to which are only aroused when they threaten to affect directly the social and ethical habits of society. It was because Galileo showed that the earth was only an inconsiderable member of the sidereal universe, and therefore could not be the main object of God's creation, that the outcry against him arose. Similarly, in the middle of the nineteenth century, it was not the change of one species of animal into another that outraged public feeling, but the theory that man was sprung from the lower animals, with the supposed bearings of this theory on such doctrines as the immortality of the soul.

Prof. More has some severe things to say about the "bluff" with which the propaganda in favour of evolution in the middle of the nineteenth century was conducted. The public were assured that natural selection was an all-sufficient explanation of the development of life, and that thought was nothing but molecular motion. Those who dared to raise

such questions as to how a negative process like selection, which is only a pruning-knife, could originate anything new, or how thought and knowledge, if they were merely accidental concomitants of molecular disturbance, could tell us anything of the external world, were shouted down. Prof. More deprecates the hero-worship of Huxley; and Huxley would certainly have disclaimed it for himself. Huxley, as Prof. More shows, was intensely human; he promulgated inconsistent views at different times; at one time declaring that the geological record was so imperfect that it could prove nothing about evolution, and at another founding the whole of the case for evolution on palæontology. Sometimes he preached pure materialism, and at other times he acknowledged that matter was inconceivable without mind to picture it in—which is simply Berkeleyan idealism. Prof. More also objects to Huxley's constant iteration of the purity of his love for truth—as More says, this savoured of brag, because it implied that he alone sought the truth and that his opponents did not.

Prof. More then gives a searching and critical exposition of the history of biological thought in ancient times: he is rather severe on his fellow-countryman, Prof. Osborn, whom he convicts of a very superficial acquaintance with the classics. For he points out that neither the Greeks nor the early fathers of the Church, whom Osborn had claimed as forerunners of Darwin, had the remotest conception of evolution. According to Prof. More, the idea that various groups of animals originated from a common ancestor could only arise when it became clear that fossil species had existed, different from those now living, otherwise why should we not assume that all the inhabitants of the earth began their existence together?

Coming to more modern times, Prof. More discusses the theories of Lamarck and Darwin and confesses himself strongly attracted to the former. He criticises some of Lamarck's ideas, such as his distinction between the action of God and of natural law, but he thinks that if experimental research bore out Lamarck's assumptions (and we hold that it does), then there would be little to say against the theory. When he comes to Darwin he deprecates hero-worship in his case just as in Huxley's case. He points out that the idea of natural selection came into Darwin's mind as a sudden suggestion when he was a young man, and that he devoted the rest of his life to the attempt to prove it to be true, so that his scientific method was deductive and not inductive. He is severe on Darwin's assumption that the aberrations of domestic animals are of the same nature as the adaptations of species, and he points out that Darwin was devoid of any training in the philosophic criticism of his own

ideas and did not realise that selection explained nothing and that his theory was really a theory of the constant occurrence of small inheritable variations in all directions (which the pure-line experiments have shown to be baseless).

In Great Britain the scientific bluff of the nineteenth century has been detected and discounted, with the result that the broad theory of evolution has been generally accepted by all the educated classes, and its acceptance is not regarded as involving a materialistic philosophy. But fashions in thought, as in clothes, often originate in Britain and are afterwards transferred to America, where they continue to flourish after they have become somewhat *démodé* here, and to judge from Prof. More's quotations, a crude mechanistic philosophy of life is still rampant in America. For in the last analysis we come down to the two alternatives: either what we call life, the external manifestations of which are concatenations of physical and chemical forces, is due to the arrangement of atoms in the living substance, or else it is due to the operations of an invisible entelechy or psychoid which uses and arranges these forces to gain a definite end.

Prof. More, who is a physicist himself, is mercilessly severe on the bad physics and worse chemistry with which the mechanistic biologists strive to cloak the inadequacy of their explanations. When the attempt of Verworn to show that the action of each living being was the result of its protoplasm containing a characteristic type of molecule (the mythical biogen) broke down and it became obvious that protoplasm is not a characteristic compound but a characteristic mixture of compounds, the difficulty of explaining how the typical proportions of this mixture were maintained became insuperable. The absurdity of some of the attempts to overcome this difficulty quoted by Prof. More, is almost incredible, as, for example, that of Prof. Ritter who maintains that every individual organism is a chemical compound! It is against the mechanistic view and not against evolution in general that Prof. More's whole polemic is directed, and he concludes with two chapters on "Evolution and Society" and "Evolution and Religion."

In the first of these chapters, Prof. More shows the impossibility of reducing sociology to the status of a definite science governed by fixed laws. He points out how all the prophecies of sociologists of the Spencerian type are being falsified by the trend of events, and that society in general does not "evolve" by the work of natural selection on the masses, but by the sporadic appearance of really great men and their incalculable influence on their fellow-humans. In the concluding chapter he develops this subject

further: he says that in the spiritual realm we do not observe regular progress, but extraordinary and unaccountable breaks; that no theory of evolution will account for Jesus, St. Francis of Assisi, or Pascal (nor, we may add, for Mahomet or Buddha), and that the wider acceptance of the theory of evolution has not led to moral progress as Spencer predicted that it would do. We may conclude this review by a quotation from this chapter: "If it were a general law that homogeneity changes to heterogeneity then all primitive stocks should progress if sufficient time be given. The contrary is the rule. Only a few primitive stocks have shown the power to progress to a high civilisation. . . . Unless they (the remainder) fall under the constraint of a foreign dominating stock we see no signs that they would ever advance to a complex or heterogeneous social state."

Is not Prof. Elliot Smith right after all?

E. W. M.

Lodge on Radio Communication.

Talks about Wireless: with some Pioneering History and some Hints and Calculations for Wireless Amateurs.

By Sir Oliver Lodge. Pp. xiii + 251. (London, New York, Toronto and Melbourne: Cassell and Co., Ltd., 1925.) 5s. net.

THE author in his preface describes this book as a friendly book. It is a message of greeting from one of the pioneers of the art of radio communication to the many who are following in his footsteps. He would be hard to please who did not find something acceptable and worthy of thought in these interesting chapters. The first part of the book describes radio in general. The second part gives hints that make for efficiency, and the final part gives methods of calculation which will be helpful to amateur constructors.

We have read the book with much pleasure. It is of great value to have on record views of the early history of radio communication by one who took a leading part in making that history. The book makes no pretence to be a complete history, but we think that the author has laid due stress on those discoveries and inventions which played a leading part in radio development.

No one has a more open mind than Sir Oliver Lodge. He is willing to investigate any phenomenon although it seems to contradict physical principles almost universally accepted. This attitude of mind is admirable. His statements, however, about the ether are perhaps too dogmatic. He believes firmly in the ether of space as a continuous reality which welds not only us but all the planets into a coherent system. "We are utilising it every day of our lives, and it would

be ungrateful as well as benighted if we failed to render due homage to its omnipresent reality and highly efficient properties." We think that this is putting belief in the ether on too high a level. Like the planetary electron, it is still unfortunately in the region of metaphysics. The hypothesis has proved of the greatest value in the past. It greatly simplifies our physical explanations of light, electricity, and gravitation, and no physicist hesitates to use it. But we must still recognise that it is only a hypothesis and be ready to change our views if anything more useful and convincing is suggested. It is advisable to take up a humble attitude.

Sir Oliver is enthusiastic about the modern methods of rapid transport and the greatly increased facilities for communication between inhabitants of this planet. But he points out that much more than physical and material progress are wanted before the much-desired, but long-delayed, era of universal peace can come. An essential preliminary is that every one should have a whole-hearted desire for the co-operative advancement of all nations on terms of mutual amity and goodwill. "Now that we are able to travel farther and faster, we should travel to some good purpose. And now that we can speak across a continent, let us see to it that we have something worthy to say."

It is perhaps going too far to state that we have extended the range of human speech to distances undreamt of by our ancestors. It is interesting to remember that the ancient Greeks contemplated not only the possibility of speech being heard at places hundreds of miles apart, but also that some of them believed that one at least of their philosophers could "broadcast." It is recorded that Pythagoras could be heard lecturing by different audiences in different towns on the same day and at the same hour. Whether Pythagoras anticipated Sir Oliver as a broadcaster or not, it shows that some ancient Greeks had considered the possibility and the effects produced by broadcasting. Unfortunately, the story of Pythagoras, who flourished about 500 B.C., is shrouded in the dim magnificence of legends.

The author points out that Joseph Henry in 1842 had the genius to surmise that there was some similarity between the ethereal disturbance caused by the discharge of a Leyden jar and that caused by ordinary light. In 1875, Edison observed that when an electric discharge took place, sparks ensued between neighbouring conductors, and Elihu Thomson investigated this phenomenon. A very important step forward was made in 1897 when Lodge showed how to obtain accurate tuning by the use of a coil of variable inductance. He also considered the possibility of transformer reception. Further great advances were made

by Fleming and Lee de Forest. Those of us who can remember the difficulties of reception twenty years ago regard the present easy methods of getting excellent reception as almost miraculous.

Many hints are given in Part II. which will prove useful to the amateur. He should use only wire of the highest conductivity, thoroughly insulate all his appliances, and make all joints as perfectly conducting as possible. Excellent chapters are given on the various methods of aerial excitation and on the grid as a "traffic regulator."

In the final part of the book, calculations are given suitable for amateur constructors. Stress is laid on the fact that the maximum possible inductance that can be obtained from a wire of length l is $3\pi nl$, where n is the number of turns of wire. If the inductance of the coil is not equal to $3\pi nl$, then it has not been properly made. Maxwell pointed out that it has this value when the radius of the circular section of the coil is 3.22 times the radius of the cross section. But in this case the formula from which the maximum value was deduced is only a rough approximation. If we take the much more accurate formula given by Rayleigh, we find that the ordinary method gives a result which is about 3 per cent. too small. The methods given of calculating the capacity of the aerial are only rough approximations and merely show the order of the magnitude of this quantity. The reviewer finds it very difficult to understand what radio engineers mean by the capacity of an aerial, although he has investigated several empirical formulæ which give results agreeing closely with measurements.

A. RUSSELL.

Liquid Fuels from Coal.

The Conversion of Coal into Oils. By Dr. Franz Fischer. Authorised English translation, edited with a Foreword and Notes, by Dr. R. Lessing. Pp. 284. (London: Ernest Benn, Ltd., 1925) 36s. net.

IN view of the fact that there are no appreciable sources of natural petroleum in Great Britain, and that the country is therefore dependent on overseas supplies for all its rapidly growing requirements, the importance of studying methods whereby substitutes could be provided by treatment of raw material indigenous to Britain cannot be overstated. The technical problems involved are being studied both at home and abroad by many competent workers, more especially in those countries which do not produce natural liquid fuel. Inquiry is also stimulated, even in those more fortunately situated, by the rapidly increasing demands for oil for all purposes.

During the past few years progress has been made in our knowledge of the constitution of coal both in

Great Britain and America, whilst many valuable contributions to the subject have emanated from Prof. Franz Fischer and his co-workers in the Kaiser-Wilhelm Institut für Kohlenforschung at Mülheim-Ruhr in Germany, a research institution which was inaugurated in 1914, shortly before the outbreak of the War. It is especially helpful at the present time to those workers who are seriously studying the subject to have available a translation of Dr. Fischer's work on "*Die Umwandlung der Kohle in Öle*" from one so competent to handle the subject as Dr. Lessing, himself identified with much valuable work on the constitution of coal.

In the treatise, the whole problem of the conversion of coal into liquids is critically surveyed. Naturally the book is largely concerned with the author's carefully planned researches extending over some nine years, but, at the same time, due consideration has been given to the work of other investigators, and if in certain cases the review of work in Great Britain and in America is somewhat sketchy, the fault lies in the break in the scientific relations between the various countries due to the War.

The subject matter is divided into five main sections, of which Chaps. 1 and 2 deal with the extraction of coal by solvents and the production and working of primary tar respectively. Most of the work described in these chapters has been dealt with adequately by British investigators and appears in the English literature. In Chap. 3 the hydrogenation of coal is considered at some length, but a much more extended description of the results achieved by Dr. Bergius of Mannheim might have been included. Chapters 4 (Synthetic Processes) and 5 (Hydrocarbons from Carbides) form the most valuable portion of the book, since they summarise, for the first time, the recent developments in the synthetic processes which Dr. Fischer has studied so intimately.

It is the author's evident belief that a solution of the light liquid fuel problem will, if found, lie in syntheses from the simple molecules of carbon monoxide and hydrogen, the coal being first broken down by some process and utilising the water-gas reaction to yield these molecules. He points out that "dry distillation is essentially a destructive method based on the thermal decomposition of the ulmins, and particularly of the bituminous constituents of coal," and that products of low boiling range, for which, of course, there is an almost unlimited demand, are formed only to a small extent. "The large size of the molecules of the compounds forming coal itself explains its behaviour on distillation, that is, the fact that thermal decomposition of the bitumen and the other coal constituents yields predominantly products of high boiling points." He considers, and with reason, that synthetic methods,

starting from very small molecules, are more likely to yield low boiling fuels than the method of destructive distillation.

Dr. Fischer therefore advocates first recovering the primary or low temperature tar by one of the destructive distillation processes, followed by complete gasification of the semi-coke. The gas so obtained forms the raw material for the preparation of a mixture of oxygenated synthetic oils produced from carbon monoxide by catalytic processes and which he has designated, "Synthol." This product consists of a complex mixture of diverse aliphatic compounds from which acetone, methyl-alcohol and ethyl-alcohol can if necessary be recovered by fractional distillation for use as solvents, the remainder apparently forming an excellent motor fuel. A few road tests are quoted in which comparisons are made between benzol, synthol, and various mixtures of benzol-synthol and benzol-alcohol-synthol, in which both mileage and starting properties compared favourably.

Interesting and valuable as this is as showing the possibility of obtaining from coal large quantities of lighter oils, it must not be forgotten that the process has still to be worked out commercially, and little data exist as to whether such a process can produce liquid fuels on a really large scale at a price competitive with natural fuels. In Great Britain the fuel problem is twofold, namely, to produce a solid smokeless fuel which can be burnt in existing grates, and at the same time to produce supplies of fuel oil, both light and heavy, for commercial and marine purposes. Some 35 million tons of coal per annum are burnt in the domestic grate, and should a stage be reached in which the bulk of this raw coal was subjected to preliminary carbonisation, a useful supply both of heavy and light oils would be available, but the coke would be required for household purposes. If, however, these methods can be developed successfully so as to be capable of application on a scale commensurate with the needs of a nation, there will be ample room for both, and the degree to which low temperature distillation would be combined with further treatment of the coke to produce liquid fuels would be determined in various countries according to their resources, requirements, and national habits.

In the foreword, the editor points out that he has adhered as closely as possible to the original text so far as is compatible with English phrasing. In an appendix, however, he has considered one or two of the latest developments of low temperature carbonisation, treatment of primary tars, and hydrogenation of coal, so as to indicate to his readers developments with which, for reasons already mentioned, Dr. Fischer could not be expected to be familiar. A useful bibliography

completes a work which should undoubtedly find a place in the library of the British chemists and engineers who are now working on the many-sided problem of rendering Great Britain to some extent independent of foreign sources for her supplies of liquid fuels.

C. H. L.

Botanical Text-books.

- (1) *A Class Book of Botany*. By Ernest Stenhouse. Pp. xi+514. (London: Macmillan and Co., Ltd., 1925.) 7s. 6d.
- (2) *A Textbook of General Botany*. By Prof. William H. Brown. Pp. xi+484. (Boston, New York and London: Ginn and Co., 1925.) 13s. 6d. net.

THE large variety of text-books of botany which have been published during the last few years, in Great Britain and in America, render it difficult for any addition to their number to present novelty of either treatment or subject matter. Most such works tend towards one of two extremes according as they appear to aim, on one hand, at imparting the maximum number of facts in the minimum of space, which in the hands of the inexperienced writer may lead to the endeavour to include all aspects of the subject, even perhaps insecurely founded hypotheses; or, on the other hand, the author may emphasise the more philosophical aspects of the subject, sometimes even to the exclusion of essential data. The best text-books are those which most nearly attain the balanced combination of these two aspects, and whilst subordinating facts to the illustration of principles, nevertheless provide the student with such a foundation of knowledge as shall enable him to build securely the superstructure of his later studies. It is in the selection of the illustrative data and its manner of presentation as part of a co-ordinated concept of vegetable life that the student gains by the experience of the author, provided that the latter has not forgotten with the passage of time the rungs on which he slipped as he himself climbed the ladder of progress.

The two books under review illustrate the two tendencies indicated above. In the "Class Book of Botany," by Mr. Stenhouse, we are impressed by the large amount of information which it contains, especially since it is intended for the use of those preparing for matriculation and similar junior examinations. But the facts are somewhat insistent as such, their significance and co-ordination too little emphasised. A useful feature is that each of the numerous chapters is preceded by suggestions for practical work, including many of an experimental character. Also each chapter is followed by a number of questions from examination papers.

There is much that is admirable in Mr. Stenhouse's book, but we have an ever-present consciousness as we peruse its pages that we are preparing for an examination. That it may produce successful candidates is very probable, but whether it will create lovers of the subject for its own sake is less certain. There are numerous illustrations of which the line drawings are in many cases reproductions of well-known figures, whilst the half-tone blocks have mostly been prepared from Mr. Irving's excellent plant studies. The latter are indeed the chief redeeming feature of an otherwise uninspiring chapter on common British trees. It may be noted that, apart from the ground usually covered by text-books of an elementary character, the simpler microscopic structure of plants is described, and there is a short account of a few of the common types of plant community.

(2) Prof. Brown's "Textbook of General Botany" is likewise of an elementary character and covers much the same ground. The earlier chapters treat of the various regions of the plant considered from the structural and physiological points of view, whilst the later chapters are devoted to the subdivisions of the vegetable kingdom, heredity, geographical distribution, etc.

Here the treatment is much more general in character, and occasionally one feels that the author passes too lightly over the ground, but the spirit in which the book is written is well expressed by the author's statement in the introductory chapter that "all persons should have some knowledge of botany if only for the purpose of understanding better so important a part of their environment as the vegetable kingdom." The text is well illustrated with more than five hundred original figures, mostly taken from tropical or sub-tropical material, the utility of which, however, is somewhat discounted by the lack of annotation.

The text in both of these works is divided into headed paragraphs: a device which, if it has advantages, tempts towards a discontinuity of narrative that neither author has been able to resist.

E. J. S.

Bird Islands of Peru.

Bird Islands of Peru: the Record of a Sojourn on the West Coast. By Robert Cushman Murphy. Pp. xx + 362 + 32 plates. (New York and London: G. P. Putnam's Sons, Ltd., 1925.) 15s. net.

THE western coast of South America is washed throughout a large part of its extent by a great river of cold water, an arm of the Pacific Antarctic drift. This, the Humboldt Current, has effects upon climate, vegetation, fauna, and human affairs that are no less profound than those of the Atlantic Current in

north-western Europe. It is not until within nearly three hundred miles of the equator that the cold northerly flow leaves the coast, to sweep outwards past the Galapagos and become lost in the expanses of ocean. Thus, along the Peruvian littoral we have temperatures which are very low in relation to latitude, and where tropical jungles might be expected to skirt the coastward base of the Andean range there is a strip of arid desert fringed with barren islands.

It is owing to the Humboldt Current, therefore, that this region of the tropics has a fauna with marked Antarctic affinities. In latitudes where turtles might be expected to pull out on the beaches to lay their eggs in warm sand, we find instead penguins burrowing on a barren coast. To the current also is due the great abundance of life. For a variety of reasons the waters of this ocean stream are peculiarly favourable for the multiplication of diatoms; thus for the existence of immense quantities of fishes; and thus, in turn, for vast numbers of piscivorous birds. One more fact completes the chain of circumstances. The great colonies of sea-fowl nest on the islands, and as these are barren and unwashed by rain, the excrement of the birds accumulates to form great deposits of guano. This, then, is the origin of "the greatest modern industry based upon the conservation of wild animals."

Dr. Robert Murphy, now of the American Museum of Natural History, has made these matters the theme of an entrancing book, based largely on his own experiences during an expedition which was made possible by a bequest to the Brooklyn Museum, of which he was then curator. The object of the expedition was to investigate the oceanic conditions responsible for the abundance of life in Peruvian water, and the inter-relationships and distribution of this life; to make zoological studies and collections; and to observe the conditions of the reorganised guano industry. The results are attractively set forth in narrative form, with allusions to previous writers, and are of great interest from more than one point of view. There is much of oceanography and biology, and much particularly about the birds; while native customs, antiquities, history, industrial considerations, and the incidents of travel are all given their place.

The chief guano producers are four in number, all of them belonging to the natural order Steganopodes—a cormorant, two boobies or gannets, and a pelican. Of these the *guanay* or white-breasted cormorant (*Phalacrocorax bougainvillei*) is the most important. The reader of Dr. Murphy's book will not fail to gather an impression of the almost incredible abundance of this species, and of the extent and density of their colonies—where there may be three nests to the square

yard. A single island was estimated to have a population of five and a half million birds, old and young, to maintain which it is computed that not less than a thousand tons of fish would be required every day! One of the boobies (*Sula variegata*), although not producing so much available guano, is even more numerous. The reader who has ever watched a gannet dive from the sky, to spear a fish seen in the sea beneath, will surely marvel to read of a flock of a thousand *piqueros* plunging simultaneously on passing over a shoal.

The best guano has a nitrogen content thirty-three times greater than farmyard manure, and is much more effective as a fertiliser than any synthetic compound that has been devised. Its agricultural uses were known to the Incas before the Spanish conquest, and irrigation schemes and guano together helped to make fertile the desert levels of the coast. The island deposits were in these olden days worked in a conservative manner, and the birds were strictly protected. The lesson had to be learnt again, however, for when the value of guano was realised in Europe in the middle of last century an era of reckless exploitation began: the accumulation of ages was rapidly used up, one island being lowered in level by a hundred feet, while at the same time the productive birds became greatly reduced in number, both through disturbance of their nesting places and direct destruction. The birds and the industry would both in time have been wiped out had not wiser counsels prevailed (including the advice given by a British naturalist, Dr. H. O. Forbes, and by Dr. R. E. Coker of the U.S. Bureau of Fisheries) and the industry been placed under Government control by the Peruvian authorities. Extraction is now limited in amount and regulated in accordance with a system of rotation which reduces disturbance to a minimum; the birds themselves, with careful protection against human and natural enemies, are rapidly repopulating their colonies; and the industry prospers while building up its future as it goes.

Atmospheric Electricity. •

Électricité atmosphérique. Par B. Chauveau. Troisième fascicule: Généralités sur les ions, l'ionisation et la radioactivité. La conductibilité et l'ionisation de l'atmosphère. Pp. xi+240. 22 francs. Deuxième fascicule: Le champ électrique de l'atmosphère. Pp. x+264. 25 francs. (Paris: Gaston Doin, 1924 and 1925.)

IT is a remarkable fact, and one not easy to explain, that although some of the most important contributions to our knowledge of atmospheric electricity have been made by British workers, there is no book in

the English language dealing with the subject. The need for such a treatise has been constantly felt, especially when students have expressed a desire to undertake research on some problem connected with atmospheric electricity. Until quite recently, the only books to which such students could be referred have been written in German, and this has proved a great obstacle. The position has been very much improved by the almost simultaneous publication of two works in French, which language has much less terror for the average English student. One of these, "Traité d'électricité atmosphérique et tellurique," by E. Mathias, was reviewed in NATURE so recently as August 1 last, and now M. Chauveau's book, the first part of which appeared three years ago, has been completed.

We must congratulate M. Chauveau on having written an extremely valuable account of the present state of our knowledge of the electrical phenomena of the atmosphere. He has divided his work into three parts, each published separately, but this has only been done for convenience; the work must be treated as a whole, for the parts are not complete in themselves. The first part, which is an historical introduction, has already been reviewed in NATURE (vol. 110, p. 406, September 23, 1922). The second part, which was the last to be published, deals with the electrical field of the atmosphere; and the third part with ions, ionisation, and radioactivity. It is not necessary to give a list of the subjects dealt with, for one can sum up the contents of the book by saying that every piece of work of permanent value has been considered, and references are given to practically every paper which has ever appeared on the subject.

One is grateful to M. Chauveau for the descriptions he has given of the apparatus used and of the methods employed by the various workers. His summary and co-ordination of the great mass of results obtained is masterly and could only have been accomplished by one who has himself made a life's study of the subject.

On reading this book, the outstanding impression which remains with the reader is the enormous number of problems which are still unsolved. One has the feeling that we have as yet done little more than discover a large mass of almost unrelated facts. The only thing which seems to be common to all is the factor of electricity. The surface of the earth has a negative charge which undergoes daily and annual changes, to say nothing of abnormal variations due to meteorological factors; but we do not know whence this charge comes, nor how it is maintained; we do not know the cause of the daily or the annual variation; we do not even know whether these periodic changes are of a terrestrial or cosmical origin.

Then again, the air is ionised, but we do not know why it is ionised. The presence of radioactive constituents in the atmosphere would appear to offer a solution to this particular difficulty, but when we examine the matter more closely we find that the problem is not solved. The amount of radioactive matter is nearly ten times as great over the land as over the sea, yet the ionisation is practically the same over the centres of the oceans as over the continents. No one has yet proved a numerical correlation between the amount of radioactivity in the air and the state of ionisation.

What part does ionisation play in the whole phenomena? The amount of ionisation obviously affects the rate of loss of electricity from the surface, but does it determine the magnitude of the remaining charge? If so, and there is some evidence that it does, is the daily and annual variation of the potential gradient simply due to the daily and annual variation of the ionisation? For this there is as yet no evidence. In this connexion M. Chauveau appears to ascribe a rather more important rôle to the large ions than is usually done by other writers.

If the maintenance of the earth's negative charge is the greatest problem, the mechanism of the thunderstorm, with which the origin of the electricity associated with atmospheric precipitation is intimately bound up, runs it very close. M. Chauveau's treatment of this branch of the subject is very complete, and his description of the observational work is excellent. He is, however, not satisfied that the true mechanism of the thunderstorm has yet been discovered.

These are only a few of the problems still unsolved; the book is full of others to which we have not space to refer. We can only recommend that every one interested in the subject, especially those undertaking further investigation, should study this book very carefully.

- Modern Medical Monographs. (London, Bombay and Sydney: Constable and Co., Ltd., 1924.)

THE rapid advance of scientific, as opposed to empirical, medicine has stimulated Prof. H. MacLean to edit a number of monographs dealing with subjects in which the average medical man, who cannot remain in contact

personally with the progress of all branches of his profession, must yet maintain his knowledge at a modern standard. In the first three monographs published, the editor and authors have succeeded admirably in presenting modern views with a brevity and clearness which will prove a great attraction to the medical practitioner.

(1) The first volume under notice carries the admitted authority of Colonel Harrison. It contains references to every clinical and pathological detail in the diagnosis of venereal disease, and clear guidance through the confusing list of drugs now used in its treatment. It is certainly the best book of its size on this subject.

(2) Dr. Wingfield's work is offered to the senior student and to the general practitioner; junior students are recommended to turn elsewhere for the basis of their knowledge of phthisis, and in view of the limited amount of clinical data given, this is sound advice. The greater part of the book is devoted to treatment, but as this is always considered in association with the patient's condition, clinical features are not neglected. Dr. Wingfield is an exponent of treatment by graduated exercise, and gives a good account of the successful methods adopted at the Brompton Sanatorium, Frimley. Fresh air is considered of value only from the point of view of improving the general health, and sunlight is only mentioned casually. A most valuable chapter for the practitioner is that on after-care, including rules for the estimation of progress. The book is well illustrated by X-ray photographs.

(3) The third work under notice is of necessity a much less dogmatic book. Here the authors can only sum up the progress made by research into an obscure though important subject; conclusions are more provisional, and practical help for those who have to treat the disease is scanty. This is consequent on the absence of any definite knowledge of the pathology of pregnancy toxæmias, and the authors have made the best of a difficult task. In the treatment of eclampsia, they are not in favour of terminating pregnancy except in very toxic cases, where Cæsarian section is recommended; in other cases they advise morphia, washing out the stomach, and an enema, but no other interference.

Animals in the Making: an Introduction to the Study of Development. By J. A. Dell. (Bell's Natural Science Series.) Pp. xii + 115 + 8 plates. (London: G. Bell and Sons, Ltd., 1925.) 2s. 6d.

THE appearance of this little book is most opportune. The teaching of biology in schools, as an introduction to the proper understanding of the reproductive processes in man, is being urged insistently by biologists, and the time seems to be approaching rapidly when biology will take its proper place in the school curriculum. The author of this book, himself engaged in school work and therefore familiar with the practical difficulties of teaching the subject to children, has here drawn up a course of quite easy laboratory exercises, designed to allow pupils to see and handle for themselves embryological material to illustrate the fundamental principles of animal development. The exercises are very simply conceived and are such as can, with ease and very little expense, be carried out in any school with the minimum of apparatus. They include elementary observations and measurements on growth,

and the principles and use of the simple lens and microscope.

With these aids to study, the development of the frog, fowl, and rabbit are followed through on living material, step by step, and the changes observed correlated with change in habits and mode of life. The full course is planned to occupy a year, and at the end of that time the pupil has gained a considerable insight into the processes of development, fertilisation, and growth, the nourishment of the young, and even into the cellular structure of animals. Such an insight cannot fail to be of the greatest value to the child as a preliminary to an understanding of the essential facts of human development. The author is to be congratulated on the production of an excellent little book which should be of real help to countless other teachers who are anxious to extend biological teaching in schools.

Ancient Warriors of the North Pacific: the Haidas, their Laws, Customs and Legends, with some Historical Account of the Queen Charlotte Islands. By Charles Harrison. Pp. 222 + 11 plates. (London: H. F. and G. Witherby, 1925.) 15s. net.

FOR a missionary who has spent forty years among the Haida, this must be regarded as a rather unsatisfactory book. There is no question as to the accuracy of what is stated, but it is slight and there is insufficient information concerning the social life and social organisation of the people. The title of the book would lead one to expect some account of their fighting and warlike expeditions, but the information on this aspect of their life is very meagre. The most satisfactory sections are those dealing with the shaman and his medical and other activities. The religious beliefs are dealt with. A brief account is given of the history, geography, natural history, and geology of the Queen Charlotte Islands, and also of their natural resources. In an appendix, measurements by Dr. Oettinger are given of a few crania.

The author claims that "these islands are a great reservoir of potential wealth and that as the demands of the civilised world increase their natural resources will be developed." Earlier in the book he says of the Haida: "They were once a powerful nation and the terror of all the surrounding tribes. One hundred years ago they were numbered by tens of thousands; now only about one thousand can be found. . . . Their history is only another example of the inability of the North American Indian race to survive in contact with European civilisation." Presumably Mr. Harrison considers that the Haida will have quite disappeared before the country is systematically exploited, but if he has any wish that "undoubtedly the finest and most intelligent race on the coast" shall continue to exist, his suggestion does not appear to be the best way to preserve them.

Grundzüge der Kolloidlehre. Von Prof. Dr. Herbert Freundlich. Pp. viii + 157. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1924.) 6 gold marks.

THIS book is written as a strictly non-mathematical introduction to colloid chemistry. The author's classical work, "Kapillarchemie," is mathematical, extensive, and designed for the advanced student and

investigator. By abbreviation and excision of mathematical deductions and numerical data, a very much smaller book has been prepared. It is easy to read, introduces the fundamental points, and can be heartily recommended as a sound, interesting, and adequate survey of elementary, theoretical colloid chemistry.

The subjects dealt with include the phenomena at interfaces (liquid/gas, liquid/liquid, solid/gas, solid/liquid), such as surface tension, adsorption, capillary-electric phenomena, and the properties of interfacial layers. The Brownian motion is discussed historically, and then are outlined the general properties of sols and gels, including the problem of the Liesegang rings. Brief accounts of clouds and smokes, and emulsions and foams, complete this useful introduction to the author's detailed book.

The reviewer takes exception to the statement (p. 165) relating to emulsions: "When one liquid is in considerable excess, it necessarily becomes the dispersion medium." The literature on colloidal chemistry records several examples of even 99 per cent. of one liquid being dispersed in 1 per cent. of another liquid. Also, both types of such concentrated emulsions are known, namely, oil-in-water and water-in-oil.

WILLIAM CLAYTON.

Die Kriegsschauplatze 1914-1918 geologisch dargestellt.

Herausgegeben von Dr. J. Wilser. (In 13 Heften.) Heft 1: Elsass. Von Prof. Dr. E. Kraus und Dr. W. Wagner. Pp. viii + 154 + 3 Tafeln. (Berlin: Gebrüder Borntraeger, 1924.) 13s. 2d.

KRAUS and Wagner's "Elsass" is the first in number of a series of monographs on the geology of some chief fields of the War. It shows the extent to which the German military staff used geological help. The series includes contributions to the geology of several areas in Europe of special interest which had been inadequately studied. Elsass, however, was geologically well known, though the province is tectonically complex because the Alpine movements have been superimposed on the older Variscan structure. The authors deal with the province in three divisions. In the North Vosges, pre-Cambrian gneisses and Cambrian rocks have both been folded by the Caledonian movements and succeeded by deposits ranging from middle Devonian to the Trias. In the Middle and South Vosges the gneisses are directly covered by Lower Carboniferous rocks; they have been altered by granites intruded during the Variscan disturbances which were followed by the deposition of the Permian and the Trias. The third region is the rift-valley of the Rhine with Oligocene, Pliocene, and Pleistocene deposits. The monograph contributes much fresh information, as well as summarising the evidence on these three important geological divisions.

Outlines of the Occurrence and Geology of Petroleum: an Introductory Handbook. By I. A. Stigand. With an Appendix on Geophysical Methods as applied to Oil-finding, by Dr. M. Mühlberg. (Griffin's Mining Series.) Pp. x + 246. (London: C. Griffin and Co., Ltd., 1925.) 10s. 6d. net.

MR. STIGAND's handbook is one of the most generally satisfactory of the many smaller works now available regarding the geology of oil. In the discussion of the

origin of petroleum he concludes that it comes from many different sources, but that the bulk of it is due to micro-organisms. The chapter on field structures is admirably clear and does not attach to anticlines the exaggerated importance often assigned to them. The author is optimistic as to the quantity of oil available; he gives a long list, stratigraphically arranged, of oil-bearing localities, and if most of them were to become important producers the future supply of mineral oil would be assured; but many of the places in the list will probably not yield oil in quantities of commercial importance. The author lays on the mineralogists the responsibility for the denial that coal is a mineral, whereas reference to the text-books by Miers, the two by Dana, and the handbooks of the Mineralogical Department of the British Museum would show that the mineralogists are not the authors of the definition which leads to that ludicrous conclusion. The most important part of the work is an appendix on oil-field survey by the torsion balance, by magnetic and electric methods, by the use of seismic and acoustic observations, and of radioactivity. There is a useful bibliography on this branch of oil prospecting.

Physical Chemistry: its Bearing on Biology and Medicine. By Prof. James C. Philip. Third edition. Pp. vii + 367. (London: E. Arnold and Co., 1925.) 8s. 6d. net.

THE principal new feature of the third edition of Prof. Philip's book is the increased attention which has been paid to problems relating to hydrogen-ion concentration—a purely physical conception which has proved of such value in biological problems that its development has been very largely due to the intensive study of the phenomenon by physiologists. References to recent work have also been given; however, in other directions, and additional matter in reference to the properties of membranes has been inserted.

Distillation in Practice. By C. Elliott. (Chemical Engineering Library: Second Series.) Pp. 188. (London: Ernest Benn, Ltd., 1925.) 6s. net.

MR. ELLIOTT's monograph forms a useful supplement to his "Distillation Principles," recently noticed in NATURE. The first five chapters consider the operation of the fractionating column with mixtures of two components. Accounts are then given of distillation apparatus, and the cases of ethyl alcohol, petroleum, and coal tar are specially considered. References to recent literature are given.

Organic Syntheses: an Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Edited by Oliver Kamm, Roger Adams, H. T. Clarke, J. B. Conant, C. S. Marvel, F. C. Whitmore. Vol. 4. Pp. vii + 89. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1925.) 7s. 6d. net.

THE fifth volume of this excellent series includes twenty-eight preparations, among which are cupferron, ketene, pyruvic acid, and triphenylmethane. It is indispensable to all who have to carry out preparative work in organic chemistry.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Losses in Trout Fry after Distribution.

MAY I ask the co-operation of readers of NATURE—fish culturists and anglers—in testing the reliability of some experiments which were designed to ascertain the numbers of trout fry which survived out of a given number distributed in depleted trout streams? The importance of the experiments can scarcely be overestimated, because if corroboration of the Board's results is obtained in different parts of Canada and in the United States, then, if economic results are aimed at, fry will have to be rigidly excluded from all waters excepting those which are known to be suitable.

Three public bodies in Canada co-operated in carrying out the experiments during the summers of 1923 and 1924: (1) The Ontario Department of Fisheries, which furnished the fry and fingerlings and in most cases distributed them; (2) the Department of Fisheries, Ottawa, which appointed an experienced hatchery officer to check the determination of losses; and (3) the Biological Board of Canada, which appointed Mr. H. C. White to carry out the operations in the field.

In 7 streams and 2 ponds a total of 95,700 fry or fingerlings were planted, some in June of 1923, and some again in June of 1924. In 6 of the streams the losses were apparently total at the end of three months. In streams and ponds combined, apparently only 1375 survived, being less than $1\frac{1}{2}$ per cent. of the total fry planted.

The method of determining the losses was that of seining the streams or ponds and counting the survivors. A net fine enough to catch the smallest fry, and long enough to stretch across a brook, is used. A stout brail or stick, about 3 or 4 feet long, is attached to each end of the net. Heavy leads are fixed to the lower side of the net, so that fry may not escape at the bottom. The upper side is held above the water by the two men who operate the net, one on each side of the stream.

The seining should be done over and over again—a dozen or more times if necessary, in fact, often enough to ensure that almost every survivor is caught. Towards the end of the seining it may be necessary to have a third man rile the water thoroughly by stirring up the bottom of the stream in advance of the two seiners. This was done in order to prevent the fry from seeing and avoiding the net. Some practice is necessary in seining, otherwise the results will be untrustworthy.

In one of the brooks seined by the Board it was found that the fry ascended the stream about 40 rods above and 90 rods below the point of distribution. If it is desired to shorten the distance to be seined, and catch all ascending and descending fry, then two fine wire screens should be placed across the stream, one, say, 20 to 50 rods above, and the other 20 to 50 rods below the point of distribution. In each of these screens there should be inserted a cylindrical wire fish-trap, funnel-shaped at one end and joined by a smaller cylindrical wire tube or sleeve to an opening in the central part of the screen, so that the trap can be removed and cleaned at pleasure. The screen and the trap should be carefully constructed so as to catch all ascending or descending

fry, and thus discover how many fry migrate up or down stream.

The outstanding causes for the high mortality which was found in south-west Ontario seemed (1) warm, stagnant, or peaty water; (2) enemy fish eating the fry, as shown by finding fry or fingerlings in their stomachs, and (3) lack of sufficient natural food.

The results of the Board's experiments thus far are a severe condemnation, not of fish culture as a whole, but of the prevailing method of distributing fry in streams, namely, dumping them at any point most convenient to a highway or travelled road. They should be distributed with fair uniformity along the upper stretches of streams or along the margin of ponds where trout naturally lay their eggs, if they can find suitable spawning beds.

The experiments demonstrate, or at least indicate: (1) a loss of 98 per cent. of the fry (for the method of planting used and the streams investigated) during the first three months after distribution; (2) consequently a greatly increased cost of production per fry; (3) the necessity of a thorough examination as to the suitability of every stream or pond in which it is proposed to plant fry.

At present we are planting fry in the dark, and in some cases we are feeding them to coarse or useless fish.

A. P. KNIGHT

(Chairman, Biological Board of Canada).

September 8.

"Bordered" Squares of Fifth Order and their Magic Derivatives.

FIG. 1 is an ordinary "Bordered" square consisting of a "Heart" (in the associated position, the three rows, three columns and two diagonals of which sum to 39) and a "Border" formed of complementary numbers (25, 1, 24, 2, 23, 3, etc.). There are 26 such "Hearts" and 605 "Borders," and, including inversions of the "Borders" and reversions of the "Hearts," there are 174,240 squares of this type with one inversion that has a similar number. These "Hearts" can be in 21 positions in a square of fifth order, and altogether with these "Hearts" in all their positions, I have calculated that there are more than 649,000 squares of fifth order of this type of "Heart."

The above, however, are not the only kind of "Hearts." Fig. 2 shows another where the diagonals are not magic, that is, do not sum to 39 and do not have their complementary numbers in the heart. These are used for the corner numbers of the completed square. There are 135 such "Hearts" and 306 "Borders," giving a total of 88,128 squares with one inversion giving an equal amount. How many there are in the remaining 19 positions is quite unknown.

Fig. 3 shows still another kind of "Heart," where the diagonals are irregular and the number 13 is not in the "Heart." Thus the type of square of Figs. 1 and 2 is not feasible, but other positions of the "Heart" are practicable (see Fig. 3). There are only 12 such "Hearts" including the complementary "Heart," and the number of squares in all the different positions of the heart quite unknown.

So far in a square of fifth order, in a row or column the sum of the numbers of the "Heart" to the rest of the row or column has been as 39 : 26. But these are not the only proportions, and with certain exceptions all the proportions from 38 : 27 down to 26 : 39 can be made. The exceptions are 28 : 37 and 27 : 38, for which I have been unable to make "Hearts" under the conditions required. If in these squares each number be subtracted from 26, then the proportions

40:25 up to 52:13 can be obtained with the exceptions of 50:15 and 51:14 corresponding to 28:37 and 27:38. But none of these squares can be of the types of Figs. 1 and 2. The remaining figures give a square of these different proportions, and I have tried to illustrate some of the different possible positions of a heart in a square of fifth order.

Thus the number of "Bordered Squares and their

Derivatives" is very great, and if other known squares are included, such as pandiagonal squares, associated squares and their variations, rectangle squares, etc., the grand total of magic squares of fifth order, the 5 rows and 5 columns and 2 diagonals of which are magic, easily exceeds 1,000,000. I have accounted for more than a million myself, and that is without the many squares indicated above as unknown, the enumeration of which would be very laborious and intricate.

J. C. BURNETT.

On the Spark Spectrum of Lithium.

In a letter to the editor of this journal (NATURE, Feb. 7, 1925, p. 191) an account was given of a method for excitation of spark spectra, by which a vapour jet of the substance under examination is exposed to bombardment by electrons from an incandescent wire. During the development of the apparatus

certain modifications were introduced with the result that a very intense source of light has been obtained. Under ordinary conditions the current through the discharge chamber is of the order of 1 amp. and can be maintained during several hours. It has furthermore been possible to work with this discharge apparatus in connexion with a vacuum spectrograph manufactured by Adam Hilger, Ltd., in such a way that no fluorite windows are introduced in the path of light.

With this apparatus the investigation of the spark spectrum of lithium described in the former note has been continued, and it has especially been possible to extend the classification of the spectrum denoted by Schuler as the doublet system of the Li II spectrum by inclusion of a number of further lines. Table I. gives a survey of the hitherto observed lines belonging to this system. The lines marked with an asterisk were not given in my former letter. An estimate of the intensities of the lines, as they appear on the plates, is added in brackets.

TABLE I.

5484.7 (8)	2s-2p	*2657.3 (1½)	3p-6s
4881.3 (2½)	3p-4s	*2605.1 (1½)	3p-6d
4671.8 (3½)	3d-4f	*2507.0 (1½)	3d-7f
4325.7 (3)	3p-4d	*2430.0 (1)	3p-7s
3684.1 (2)	3s-4p	*2402.3 (1)	3p-7d
3195.8 (3)	3d-5f	*2381.6 (½)	3d-8f
3155.4 (2)	3p-5s	*2330.0 (½)	3s-6p
3029.1 (2½)	3p-5d	*1653.3 (6)	2p-3s
2728.4 (2)	3d-6f	*1493.1 (4)	2p-3d
*2674.4 (2)	3s-5p	*1198.0 (5)	2s-3p

TABLE II.

2s = 134,033 ($n^* = 1.810$)	3d = 48,834 ($n^* = 2.998$)
3s = 55,318 ($n^* = 2.817$)	4d = 27,467 ($n^* = 3.997$)
4s = 30,097 ($n^* = 3.819$)	5d = 17,574 ($n^* = 4.997$)
5s = 18,895 ($n^* = 4.820$)	6d = 12,203 ($n^* = 5.997$)
6s = 12,957 ($n^* = 5.820$)	7d = 8,964 ($n^* = 6.997$)
7s = 9,438 ($n^* = 6.819$)	
2p = 115,806 ($n^* = 1.947$)	4f = 27,435 ($n^* = 4.000$)
3p = 50,578 ($n^* = 2.946$)	5f = 17,552 ($n^* = 5.000$)
4p = 28,182 ($n^* = 3.946$)	6f = 12,193 ($n^* = 6.000$)
5p = 17,938 ($n^* = 4.946$)	7f = 8,958 ($n^* = 7.000$)
6p = 12,413 ($n^* = 5.946$)	8f = 6,858 ($n^* = 8.000$)

In Table II. the scheme of terms corresponding to this spectrum has been given, together with the effective quantum numbers (n^*).

It will be seen that the conclusions drawn in the former letter regarding the doublet spectrum are at all points confirmed. As regards the singlet system of Li II a few further lines in the far ultraviolet have been observed, and at the same time it has been found that several of the lines marked with an interrogation sign in Table I. of my former letter are due to impurities. It is hoped in the near future to bring a more complete term scheme of this spectrum.

Spermatogenesis in a Spider (*Amaurobius sp.*).

At the suggestion of Prof. J. Bronte Gatenby, I recently made some preparations of spider's testis, in order, if possible, to test the accuracy of the observations described by Prof. Ernest Warren in a letter to NATURE of September 12. In my preparations I have found many of the appearances figured by Prof. Warren. Fig. 1, probably corresponding to Prof. Warren's Fig. 3, is an early prophase of the first spermatocyte division; the clumps of chromatin are the first appearance of the chromosomes, and one

clump (x), which is larger than the others, is presumably the sex chromosome. Fig. 2 shows a leptotene stage, Fig. 3 syndesis, and Fig. 4 a contraction figure in the diplotene stage. In all these, the sex chromosome can be easily distinguished, and in Fig. 5, which shows the chromosomes arranged on a normal spindle, the sex chromosome is seen lying apart in the cytoplasm. Fig. 6 shows the telophase of this division. The second spermatocyte division also appears to be normal.

There are, however, two kinds of spermatids; the larger, shown in Fig. 7, arises from the ordinary divisions described above, and gives rise to a normal spermatozoon; early phases of spermatoleosis are shown in Figs. 7 and 9. The smaller type of spermatid has a very small amount of cytoplasm; these

apparently abnormal spermatids supposedly arise either by an extra division of the ordinary spermatids, or by degeneration of the normal forms. It is thus plain that in the spider examined by me the whole course of spermatogenesis corresponds with that known in the great majority of animals; there is no evidence of amitosis either in the spermatogonial or spermatocyte divisions. Abnormal spermatids are known to occur in many insects and molluscs, and occasionally occur also in mammals. In such cases, however, the testis is found to contain normal spermatozoa, which presumably are the agents in fertilisation.

Birth-Control among the New Zealand Maori.

MAY I, as a New Zealander, make a few comments on Prof. J. S. Huxley's very valuable review of "The Ethics of Birth-Control" (NATURE, September 26, p. 455). Europeans have found it almost impossible to elicit definite information from the New Zealand Maori regarding methods of control, although we have known quite well that control of fertility was exercised, and abortion is prohibited by the Maori Sacred Legends. Very few Maori women have more than four children; many fewer than four. In ancient times there was a betrothal for about eight or ten years, during which time no children were born. This betrothal was really a trial marriage. At the age of from twenty-five to twenty-eight, formal marriage took place between the betrothed lovers or otherwise, and the married woman had as many children as she desired, and by whatever father she desired.

Race improvement was taught in the Sacred Legends, and it was regarded as the duty of every mother to have as fine a father as possible for her child. If she wanted to live with her husband but preferred some other man to become the father of her child, she might allege that this lover's spirit

visited her. This was a recognised polite fiction. The husband might feel sorry his wife considered some other man a better potential father, but still he regarded himself as fortunate if his wife continued to love him and want him as her husband.

No man and no woman were allowed to reproduce unless passed as fit for reproduction by the Maori authorities; and before betrothal occurred there was medical examination of both parties by the parents of the young couple and by the doctors. Children were named by the community in accordance with their birth and form, and the girl-baby of a mother having difficult or abnormal childbirth was named in such a way as to indicate her unfitness for reproduction. Only the physically perfect men were permitted to become fathers, and no Maori woman

would allow herself to bear children by other men than these. The Maori considered the father of more importance than the mother in the matter of race improvement. Even crippled women might be allowed to become mothers, but crippled fathers—never. Scarcely any really "unfit" babies were born, but should such an accident occur, the new-born unfit baby was given "The Peaceful Death." Marriages were generally for life, and polygamy was rare. There were usually more men than women in Maori communities. Sexual hygiene and control were exercised. Some of these

practices I have detailed in "Safe Marriage" and "Sex and Exercise" (Heinemann's Medical Books); others will be detailed in "New Zealand Maori Sacred Legends," to be published shortly by Routledge and Kegan Paul.

ETTIE A. ROUT.

Choice of the Striking Point in the Pianoforte.

THE experiments dealing with the amplitudes of the partials from a struck string are many, and the conclusions are varied. For example, the experiments of W. H. George (*Phil. Mag.*, vol. 50, August 1925) show maxima at various points, and he arrives at the conclusion that the amplitude of the fundamental attains a maximum at a small distance from the bridge, while S. K. Dutta found that it attained a maximum at a distance of $1/91$, where l = length of string. Again, Berry's conclusion is that forced vibration is a maximum at $1/91$. Experiments made by me on the pianoforte have shown that the elasticity of the hammer must also be considered when calculating the duration of contact, which is of fundamental importance in the tone of the struck strings.

Recent experiments show that the amplitude of the fundamental and the octave, and the 2nd harmonic, are maximum when $T/\phi = 2$; T = period of vibration of the string, and ϕ = the duration of contact. Now ϕ depends upon the product of the striking distance and the mass of the hammer and its elasticity. The striking distance should not be very small, for then the resulting amplitude will be very small on account of the presence of the factor $\sin s\alpha/l$, where α = striking distance, and s is an integer. Secondly, it cannot be very large, for the reflection of the wave in presence of the load (hammer) would render the partials nonharmonic. Thus the striking distance must lie somewhere between $1/91$ and $1/71$. When α is fixed, the mass of the hammer and its elasticity are determinate. The best position of α is, however, obtained from the consideration of the note from the musical point of view.

Practical Engineering in Ancient Rome.¹

By THOMAS ASHBY, D.Litt.

THE Palatine, the nucleus of the City of Rome upon the Seven Hills, had great natural advantages of position; it was an almost flat-topped hill, with two distinct summits and a slight depression between them, protected by lofty cliffs, far more formidable than they seem at present, and almost entirely surrounded by two marshy valleys traversed by winding streams. Its neighbourhood to the Tiber enabled it to command the crossing, which, no doubt, existed in some form long before the foundation of Rome, probably just below the island, where the Pons Sublicius stood later. This crossing was of great importance, for it was the only permanent one over the whole lower course of the river.

Even in the palmiest days of Rome there were no bridges over the Tiber below the city, and those that there are now are all quite modern; while if we look upstream we find that above the city the only bridge for forty miles was that by which the Via Flaminia recrossed the river into Umbria just below Otricoli—and of that the last traces were obliterated by a flood some twenty years ago, which led to a complete change of course of the river. The traffic between the two banks was probably carried on by ferries, as at present.

Tradition ascribes the building of the Cloaca Maxima to a powerful race of foreign kings, the Tarquins, from the city of Tarquinii in southern Etruria. Little or nothing remains that belongs to the original structure; and indeed in the time of Plautus it was called *canalis*, and may have still been open at any rate for part of its course; for the whole this seems an almost impossibly insanitary supposition. We have, too, a number of branch drains which must have eventually led into it from the slopes of the Capitol—though conditions have been so altered that some of them now give into the open. I think they may be claimed as dating from the sixth or fifth century B.C., and as being thus by more than a century the earliest Roman arches in existence.

In this connexion I would recall that here we are dealing with a soft volcanic stone—the kind of tufa known as cappellaccio. When Appius Claudius built the Via Appia in 312 B.C., and his engineers had to build an embankment wall to carry the road along a hillside, we may see that, where they had to deal with the hard local limestone, they did not waste labour either in making a curved arch for the culvert, contenting themselves with inclining the sides gradually and then putting a lintel over, or in making the courses of the embankment wall horizontal.

The course of the Cloaca Maxima, as shown on the map, resembles, as Lanciani remarks, rather that of an Alpine torrent than of a carefully constructed drain; and its origin, from the canalisation of a stream meandering at the bottom of a flat valley, as the Tiber does at present, is sufficiently clear. The mouth of the Cloaca, with its three concentric arches of volcanic tufa, which may be assigned to 100 B.C. or a little before, was much more picturesque before the construction of the modern embankment. It is now a mere dummy, as the Cloaca itself, which still performs its functions,

has been conducted into the new main sewer (the Collettore, as it is called) which runs just inside the embankment.

The Cloaca Maxima is a drain of considerable size, having an average measurement of 14 ft. high by 11 ft. wide, while the other two principal sewers of ancient Rome are rather smaller. Both these drains were built, like the Cloaca Maxima, of large rectangular blocks of stone, with a vaulted roof of the same material; and some of the minor drains were built in the same way, while others were covered with a flat block of stone, or with two slabs inclined to form a gable. This last shape, with the gable formed of large flat tiles, was that adopted in the brick-faced concrete sewers of imperial times, which vary in width from 2 ft. to 4 ft. and in height from 6 ft. to 9 ft.

Notwithstanding their splendid construction, which still bids defiance to the lapse of time, Lanciani is undoubtedly right in maintaining that the Roman Cloacæ have been overpraised. The modern sanitary engineer cannot approve of their use for carrying off sewage and rain-water together. Such contrivances as traps and syphons being unknown, the openings for the reception of the latter served to let out the effluvia from the former. Still more dangerous was the direct admission of sewage into the Tiber, which must have been odoriferous in the extreme when the water was low; while in times of flood the drains were dammed back, as was the case even in 1902.

In the time of the Republic the drainage system was under the general control of the censors, who let out contracts for the necessary constructions or repairs in this as in other classes of public works. They also had charge of the river banks and channel, and in 54 B.C. they erected a series of boundary stones (*cippi*) along both banks to prevent encroachment by private persons. Under Augustus in 8 B.C. the consuls of the year erected another series of terminal stones, and Augustus himself a third in 7-6 B.C.

Besides the erection of boundary stones, a good deal was done in the way of actual regulation of the river bank. There was no continuous embankment wall, as at present, but walls seem to have been built at the points where they were most needed. The Romans, at one point at any rate, at the Pons Aelius built by the Emperor Hadrian (the modern Ponte S. Angelo), were wise enough to provide three different widths of channel for different seasons of the year, in correspondence with which the bridge was provided with extra flood arches. The bridge was brought to light in its entirety in 1892, and it was found that, as originally constructed, it had three arches for low water, corresponding with a channel 66½ metres wide. Two more slightly smaller arches were available when the river was moderately full, with a channel 97½ metres wide. For great floods three smaller arches came into use, giving a total width of 135 metres to the stream. It was these three smaller arches and the bridge-heads characteristically sloping up on each side that were brought to light in 1892; and it is much to be regretted that it was impossible to preserve this remarkably perfect specimen of a Roman bridge.

¹ From the presidential address delivered at Southampton on August 28 before Section H (Anthropology) of the British Association.

From the consideration of the bridges of the city of Rome we naturally pass to that of the roads. The Via Appia, the queen of roads, as Statius calls it, was built as far as Capua in 312 B.C., and later on prolonged to Venusia (291 B.C.), Tarentum, and Brundisium (244 B.C.). It runs in a practically straight line from Rome to the Alban Hills. There it finds its first serious obstacle in the small extinct volcanic crater below Aricia, where Horace spent the night *hospitio modico*, not in the high-lying town, but at the post station below; and on the steep ascent from this post station it has, on the lower side of it, a massive embankment wall, about 200 yards in length. Thus, there is little doubt, is the *Pons Aricinus*, of which Juvenal speaks as being infested by beggars—like many another steep hill. The road soon reaches its summit level at Genzano, and descends once more in a straight line along the south-eastern slopes of the Alban Hills, passing at one point of its course over a smaller embankment, almost unknown to archæologists, and then, still perfectly straight, through the Pomptine Marshes.

Thence we arrive at Terracina. Above the town is the mountain, crowned by a temple of Jupiter Anxur, behind which the old road ran, keeping high above the sea, and descending again several miles farther on. Trajan is in all probability the author of the cutting at the foot of the isolated dolomitic mass of rock at the lowest extremity of the promontory, by which the road was enabled to pass round on the level. The height of the cutting is marked in splendid Roman numerals in swallow-tail tablets at frequent intervals.

After the two roads have rejoined, there is a flat stretch for some miles, with a number of ancient culverts and bridges, still used by the modern road; and then beyond Fondi the road enters the picturesque gorge of S. Andrea, where it is supported by massive embankment walls, well seen from the modern road, which has here abandoned the ancient line.

On the descent, in the modern village of Itri, we see the "Cyclopean" wall to which I have already directed attention, and shortly afterwards reach the Bay of Gaeta and Formiæ, where Cicero had his villa. From this point onwards the road proceeded on the level. Just before the fine bridge over the Volturnus, it joined up with the Via Latina-Labicana, and crossed to Casilinum, the modern Capua. Shortly after the ancient Capua the road enters the mountains once more, and after passing through the famous defile of the Caudine Forks, we find three finely preserved ancient bridges, of which the modern road still makes use. They are probably assignable to the period of Trajan.

We soon reach Beneventum, beyond which the course of the ancient Via Appia is so doubtful that there is no question of there being any remains of great interest. We shall, therefore, do well to follow instead the Via Traiana, which Trajan built as an alternative route to Brindisi, following an older mule-track of which Strabo speaks.

The road passes through some difficult country with frequent ups and downs, and there are a number of bridges in concrete faced with fine brickwork, stone-work being used sparingly, and then only at the base of the piers. These bridges are all 24 Roman feet wide, which is more than the usual standard width (14 feet) of the Via Appia and other Roman highroads—though

even they widened out somewhat at the bridges. From the summit, about 3000 feet above sea-level, there is a long winding descent, the Buccola di Troia, to the city of Troia, the ancient Aecæ, with its fine cathedral. Here we enter the *regna arida Daunii* and the plain of Apulia. The road crossed two rivers, the Cervaro and the Carapelle, both of which have changed their course, and so left their bridges high and dry in the fields. They are, from the great width of the valleys and the character of the streams, which are wide and shallow—in fact, almost dry except in times of flood, when they carry a great quantity of water—structures of great length. The first is about 280 metres in length, about half of which is accounted for by the bridge proper, a structure with at least fourteen arches, the principal one having a span of about fifteen metres. The second is much longer, beginning with a causeway 200 or 300 metres long; then follows the bridge proper, some 200 metres long, with about ten arches; and then follows a causeway about 250 metres long, with supporting buttresses on each side.

We may turn now to the Via Flaminia, the "great north road" of ancient Rome, built by Gaius Flaminius during his censorship in 220 B.C. The Via Flaminia, unlike the Via Appia and the Via Latina, is not able to maintain its straightness of line for very long after leaving the Tiber valley. It comes into some heavy country among the hills on the right bank, but the first really serious obstacle by which it is confronted is the valley of the river Treia, which is subject to violent floods, one of which, only four years ago, carried away the modern bridge just below Civita Castellana. The valley is about 1300 yards wide, and the drop in level to the bottom is about 250 feet on the south, while the ascent on the north is some 150 feet. The difficulties were considerable, but have been very well dealt with; and the causeways and bridge by which the Roman engineers took the road across the valley form a splendid monument of their skill.

After crossing the plateau to the north, the Via Flaminia descends to the valley of the Tiber, which is followed by the railway to Florence; and here we may see its parapets still preserved beside a modern road which has recently been constructed along its line. A few miles farther on, below Otricoli, it crossed the Tiber and entered Umbria, traversing a hilly district as far as Narni, perched on a lofty cliff above the river. Ascending through the town, it reached the famous Bridge of Augustus, one of the wonders of Italy even in the sixth century after Christ, as Procopius tells us. Of the four arches by which it crossed the stream, only one is now preserved. Many other ancient bridges are preserved along the course of the road. The only other important work of which I shall speak is the tunnel by which the passage of the road through the Furlo Pass is facilitated; the inscription recording its construction by Vespasian may still be seen above the entrance.

The aqueducts of ancient Rome are among its most celebrated monuments; but, conspicuous as are their remains within the city and in its immediate neighbourhood, less is known of them at a greater distance than might have been expected. I have myself been engaged in the study of them for more than twenty-five years, and hope shortly to be able to complete the work with which I have been occupied for so long.

For the present purpose, I shall confine my attention almost entirely to the four aqueducts which drew their supplies from the upper valley of the Anio, the Anio Vetus (272-269 B.C.), Marcia (144-140 B.C.), Claudia, and Anio Novus (both built by Caligula and Claudius, A.D. 38-52)—two of them, as their name implies, taking their water from the river itself; while the other two made use of excellent and very abundant springs which are for the most part conveyed to Rome by the modern Acqua Marcia, though a few of them still gush forth freely in pools which have a beautiful bluish tint (one of the springs was, indeed, known to the Romans as *Caeruleus*). These springs, indeed, as has been ascertained by the engineers of the modern aqueduct, come from holes in the roof of the original Roman headings. They rise under the rocks at the edge of the floor of the Anio valley, only a little way above the river-level, and come probably from huge reservoirs in the interior of the mass of Monte Autore, being supplied by percolation from a great basin about 1500 metres above sea-level, which is snow-clad for the greater part of the year. As the Roman headings lie some seven or eight metres below the present level of the valley, which has been much raised by floods, it seems useless to try to identify, as previous authors have done, the individual springs of which the Romans made use.

It will be convenient to follow the course of all the four aqueducts together, observing their principal remains as they occur. The Anio Novus originally drew its water from the river four miles above the springs of the Aqua Claudia, at the forty-second mile of the Via Sublacensis; but as the water was apt to become turbid, Trajan carried out a project of Nerva, according to which the three lakes used by Nero for the adornment of his villa above Subiaco were used as filtering tanks. This increased its length considerably, the new intake being some six or seven miles farther up. Considerable remains of the dam still exist on the way up to the far-famed monasteries; but the centre of it collapsed in a flood in 1305—as the story goes, partly owing to the malice or imprudence of some of the monks who began to tamper with it. Otherwise there are no remains of any particular interest until we reach the gorge of S. Cosimato, some fifteen miles farther down. It lies a couple of miles above Vicovaro, where the road from the valley of the Digentia and Horace's Sabine farm joins the main road down the Anio valley, the ancient Via Valeria.

From Vicovaro onwards, all the four aqueducts remain on the left bank of the Anio. The deep valleys of some of its tributary streams create considerable difficulties for the aqueducts, and great bridges were required to cross them.

Farther down, the Aqua Claudia and the Anio Novus leave the river valley, and reappear in a small valley leading southward to the Valle d' Empiglione, which is traversed by the road from Tivoli to Ciciliano and Genazzano. In this valley we find only one channel (where we should expect to find two), of rough concrete, belonging to the original construction, and measuring 1.20 metre wide and 2.60 or 2.70 metres in height—characteristic dimensions of the channel of the Anio Novus when running alone. It runs along the side of the valley, so that only one external wall is exposed, and this has later facing. The same difficulty presents

itself when we reach the main Valle d' Empiglione, for whereas previous observers have supposed that the two aqueducts which are here visible can be assigned respectively to the Aqua Claudia and the Anio Novus, the line going south belonging to the construction of the tunnel under the Mons Aeflanus by Paquedius Festus in A.D. 88, mentioned in an inscription, careful investigation shows that they branch off from one another at the north edge of the valley, and that the south branch falls slightly more rapidly than the other.

The south branch is undoubtedly still attributable to Paquedius Festus, and the western to the main aqueduct; but the problem of the existence of one specus only (which confronts us again at Ponte degli Arci, though not after we have passed Tivoli) remains at present insoluble.

The level of the bottom of the specus, at the beginning of the existing arches going southward (the northern extremity of the aqueduct near the road has disappeared), is 248.57, and at the end of the bridge it has fallen to 248.17, or 40 cm. in 349 m., which represents a fall of 1 in 872.5, or 1.15 per 1000. On the western branch the levels are 249.91 at the beginning of the bridge, and 249.83 at the end, or 8 cm. in 156 m., i.e. 1 in 1950, or 0.51 per 1000. Both of these falls are below the average fall in the long stretch of arches between Capannelle (where the aqueducts emerge from their long underground course) and Rome, which varies from 3.22 to 0.96 per 1000. The general average is 2 per 1000, but there is much variation.

In the next valley to the south is the only instance known to me of the existence of an alternative channel on an aqueduct bridge, which perhaps was provided in order to allow of cleaning before the beginning of the long tunnel, in which it would naturally have been exceptionally difficult. The tunnel must be about 2½ kilometres long, and the fall is 5.90 m. to the tank where the branch rejoins the main aqueduct, or 1 in 381, or 2.62 per 1000.

We must now return to the main line, which has a fine bridge, the so-called Ponte degli Arci, over a tributary of the Anio. The original bridge was a massive structure in *opus quadratum*, most of which has disappeared, though the impressions of the blocks are visible on the pier of the great brick arch on the south-west bank, and some of the masonry itself in the base of the last pier on the north-east bank. The brickwork with which the concrete of the greater part of the bridge is faced is, once more, Severan in character. When the aqueducts emerge on the hillside above Tivoli we find the four specus distinct from one another once more.

There is a very interesting point where from a reservoir of the Anio Novus a branch channel runs off, falling sharply (about 1 in 10), and supplying when required, by means of vertical shafts, the channels of the three lower aqueducts.

After passing the point of junction of the tunnel built by Paquedius Festus, the next feature of interest is the fine bridge known as the Ponte S. Antonio, which served to carry the Anio Novus across a deep and narrow valley. We may note here a right-angled turn, which often occurs, to break the speed of the water immediately before reaching the bridge. The channel is surprisingly narrow, being only 80 centimetres wide and about 3.12 metres high. The bridge was originally

a massive structure in ashlar masonry of volcanic tufa, and the fine central arch, 32.30 metres in height and 10.40 in span, is still visible on the west side. The width was originally only 2.60 metres and the total length is about 120 metres.

In the next valley, that of the Mola di S. Gregorio, there is a long bridge of the Anio Vetus, which, however, is a construction of the time of Hadrian, itself restored later—the change of period occurs in the arch over the stream. The original channel ran underground up the north bank of the valley until it could pass under the stream, and then returned on the south bank, where its channel may still be seen. It is, after all, unlikely that in 270 B.C. the Romans would have constructed an aqueduct above-ground which could so easily have been cut by an enemy, and Augustus followed the older line in his reconstruction. The bridge has a rapid descent of 2.92 in 25.30 metres, or 1 in 8.66, or 116.5 per 1000, at the end (the only case known to me at the end of a bridge) into the newer channel, which is some six metres higher than the older channel, with which it seems to have no communication. It continues to run for some way along the valley before it turns at right angles to tunnel through the ridge separating it from the next one, that of Ponte Lupo. The bridge had a total length of about 165 metres (with a fall of 1.06 in the main portion of 136 metres, or 1 in 129, or 7.75 per 1000), and a maximum height of 24.50; it has two tiers of arches for the most part, though the last seven on the left bank originally had only one.

We now arrive at the valle of the Acqua Nera, which is crossed by the Ponte Lupo, the best-known and the largest of the aqueduct bridges in this district.

It has hitherto been believed—and Mr. Newton and I still held that view when the drawings were made—that it carried all the four aqueducts. Accurate levelling has shown that this is not the case, and that the Anio Novus and Claudia both pass under the floor of the valley considerably higher up. This, indeed, gives them a much better line than the devious course which they would have taken supposing they had passed over Ponte Lupo.

The upper channel is, therefore, that of the Aqua Marcia; the fall from Ponte S. Pietro is 186.79–182.27, or 4.52 metres in about a kilometre, or perhaps more; for the specus, as usual, runs along the side of both valleys for some way both before and after the tunnel through the ridge. But there is a problem in regard to the Anio Vetus. At the last shaft of the earlier channel in the Valle della Mola di S. Gregorio the intrados is 168.86 metres above sea-level, while at the last shaft of the newer channel, after the bridge which Hadrian built, the intrados is about 172 metres above sea-level; the floor of the specus would be about 2.80 metres lower in each case. The level of the water of the Fosso dell' Acqua Nera is 155.19, and the bottom of the specus at the Ponte Tauella is 155.61. The distance between the last two points in a straight line would be not much over two kilometres; but along the line of the aqueduct it should be 21,120 Roman feet, or more than 7 kilometres according to the *cippi*.

It is thus quite impossible that the Anio Vetus should not have been above-ground at the Acqua Nera, unless it was carried under it by a syphon. There is, about 17 metres below Ponte Lupo, on the right bank

of the stream, a massive concrete buttress, faced with *opus reticulatum*, probably belonging to the time of Augustus, and containing a shaft, which, though blocked up, certainly seems as if it went down at least as far as the level of the stream, and might very well reach down to a channel passing under it.

The question why syphons were not made use of to take the aqueducts in a straight line (like the modern Acqua Marcia) across the Campagna from Tivoli to Rome (in which they would have come to intermediate levels considerably lower than that which they reach at Porta Maggiore), in order to avoid the long detour which we are now following, has been well answered by M. Germain de Montauzan in his book on the four Roman aqueducts of Lyon, in which no less than ten syphons have been observed. The Romans did not trust their concrete and cement for making syphons, though they might have done so. They were unable to make a large metal pipe that would stand pressure; and at Lyon the contents of a channel 0.58 by 1.75 metre are transferred to nine or ten lead pipes with a bore of 0.20 when the syphon is reached. We have only to calculate the enormous quantities of lead that would have been required to take the water from four channels, the largest of which measured nearly 1.20 metre wide and 3 metres high, and to remember that small-bore pipes would have been choked almost at once by the heavy calcareous deposit, to realise how impossible it would have been to adopt this method here. On the other hand, all the building material required was quite easy to obtain on the spot or not far off. But there is no objection to its use in a rock-cut channel for a short distance; and if we do not accept this view, we have to find a place for the specus of the Anio Vetus in the lower part of Ponte Lupo; and a careful study of its construction and of the dating assigned to its various parts by Miss van Deman has shown me that this is by no means easy, though from the levels it is admissible.

Raffaello Fabretti, one of the pioneers of the investigation of the aqueducts, whose work "*De Aquis et Aquaeductibus Urbis Romae*" was first published in 1680, marks the so-called Ponti Diruti as the last remains of the aqueducts visible towards Rome; and, indeed, it was believed until a few years ago that they ran underground from this point to the well-known line of arches which begin at Capannelle. Even Prof. Lanciani had written of all the four that there were no traces from Cavamonte to Roma Vecchia and Capannelle respectively. But the casual discovery of a part of the channel of the Aqua Claudia on the farm road leading to the Casale della Pallavicina directed his attention to the possibility of discovering the course of the aqueducts in this district; and he further suggested that the large amounts of calcareous deposits thrown out at the shafts (*putei*) which occur at frequent intervals in the subterranean course of the aqueducts were bound to reveal their course still further towards Rome, where they traverse the lower slopes of the Alban Hills. This proved to be the case; and it has thus been possible to follow them from point to point in their gradual descent towards the plain, until they emerge between the Via Latina and the Via Appia.

In all this stretch, however, there were no complicated problems of engineering to be solved; and we may therefore turn to the consideration of the remains
